Öpik (Opik), Ernst Julius (1893–1985)

Born in Estonia, Öpik studied at Moscow University, and helped establish Turkestan University in Tashkent, becoming the Astronomer (director) at Tartu Observatory in Estonia. He fled the Red Army by horse cart during the Second World War and went to Armagh Observatory (Northern Ireland) in 1948. His wide-ranging interests are reflected in his discoveries and theories. These include the discovery of degenerate stars, e.g. white dwarfs, in his calculation of the density of o^2 Eridani (1915). He calculated the distance of M31 as 450 000 parsecs from the Sun (1922). He computed by hand evolutionary models of main-sequence stars into giants (1938) over a decade earlier than the computer computations of HOYLE and SCHWARZSCHILD. He predicted the density of craters on the surface of Mars, which was confirmed 15 years later by planetary probes. He put forward an unproven theory of the Ice Ages based on a calculation of changes in the convection in the internal structure of the Sun rather than MILANKOVITCH cycles.

Ångström, Anders Jonas (1814–74)

Physicist, born in Lödgö, Sweden. He was keeper of the observatory and professor at Uppsala where he studied heat, magnetism and optics and examined the spectra of the Sun and auroras. His name is commemorated with the *angstrom unit*, 10^{-10} m, which is used for measuring wavelengths of light and x-rays, and the separation of atoms in molecules and crystals.

61 Cygni

The star 61 Cygni is important because of its large proper motion, first measured at the Palermo Observatory by Giuseppe Piazzi (1746–1826). The star became popularly known as 'Piazzi's flying star'. Its measured annual proper motion of 5.23″ is still the seventh largest known, and is the largest for a naked-eye star (apparent magnitude 4.8).

This star was also the first to have its annual parallax reliably determined, by Friedrich Bessel (1784–1846). Bessel's measurement of 0.314″, made at Königsberg with Fraunhofer's 6.25 inch heliometer in 1838, compares quite well with the modern value of 0.286″. Determinations of stellar parallax made in the same year by other observers were far less accurate. It is the eleventh closest star, at a distance of 11.4 light-years.

61 Cygni is also a well-known binary system, with a period of 653.3 years. Its components are currently separated by 30.3″ at position angle 150°. The primary star 61 Cyg A is an orange dwarf, spectral type K5V, of apparent magnitude 5.20 and absolute magnitude 7.5. Its companion 61 Cyg B is also an orange dwarf, of spectral type K7V, with an apparent magnitude of 6.05 and absolute magnitude 8.3. The system is reputed to be the most extensively observed double star, some thousands of visual observations being supplemented by more than 34 000 photographic plates. Precise astrometric measurements of these plates have indicated that the system has at least one invisible component, believed to be a planet of similar mass to Jupiter, and perhaps as many as three, with orbital periods of between 5 and 12 years.

Abastumani Astrophysical Observatory

The Abastumani Astrophysical Observatory (AbAO)—longitude, 42.83; latitude, 41.81 degrees—was founded in 1932. It is located in Abastumani, in the south-west part of the Republic of Georgia, 250 km west of the capital city Tbilisi, on the top of Mount Kanobili at 1700 m.

AbAO's primary mission is to enable astronomers of the former Soviet Union to carry out high-quality observations. The average number of clear nights is 130 per year with 25% of seeings smaller than one arcsec. At present, about 100 staff members work at the Observatory in six departments and four laboratories. The Observatory's main facilities are 125 cm Ritchey–Chrétien and 70 cm meniscus telescopes.

The major research areas are accretion disks and pulsars astrophysics, solar system cosmogony, objective prism spectroscopy, low-amplitude short-period variables, AGNs variability, solar physics, solar–terrestrial phenomena and atmospheric physics.

Abbe, Ernst (1840–1905)

Born in Eisenach, Grand Duchy of Saxe-Weimar-Eisenach (now Germany), Abbe became director of the observatory at Jena and research director of the CARL ZEISS optical works in Jena. He discovered the *Abbe sine condition*, which describes a lens that will form an image, without defects of coma and spherical aberration. His mathematical treatment founded the present-day science of optics.

Abell Clusters

Abell clusters are the most conspicuous groupings of galaxies identified by George Abell on the plates of the first photographic survey made with the SCHMIDT TELESCOPE at Mount Palomar in the 1950s. Sometimes, the term Abell clusters is used as a synonym of nearby, optically selected galaxy clusters.

George Abell constructed a catalogue containing 2712 of the richest such groupings in the northern sky, which was later extended to the southern sky. It is no exaggeration to say that the total sample of 4076 cluster candidates over the whole sky has revolutionized the study of the large-scale structure in the universe. The Abell catalogue has formed the basis for the first quantitative studies of the densest component of the large-scale structure in the local universe. In recent years, the definition of samples of candidate clusters from wide-field survey plates has been repeated with automatic plate-scanning machines. This showed objectively that the subjective factor in Abell's visual selection is quite small, at least for the richer and more nearby clusters.

The reality of the cluster candidates in Abell's catalogue has been the subject of some debate, until spectroscopic observations of large numbers of galaxies in the directions of the Abell clusters showed convincingly that only a small fraction of the rich clusters are the result of chance superpositions. That is, a very large fraction of the rich cluster candidates in the catalogue made by Abell (or, including the southern clusters, by Abell, Corwin and Olowin) represent compact, localized peaks in the spatial distribution of galaxies, mostly with redshifts less than 0.2, and held together by gravity.

Already in the 1930s, Fritz ZWICKY had concluded that the luminous matter (i.e. the galaxies) in clusters represents only about 10% of the total cluster mass, most of which can therefore be detected only through its gravitation. This has led to estimates of the total mass (both visible and dark matter) by various means. The most common of those are the velocities of the galaxies in the cluster, the amount and temperature of the hot (x-ray-emitting) gas and the distortion of the images of galaxies at distances well beyond that of the cluster by GRAVITATIONAL LENSING.

For a long time, several of the better-known Abell clusters, like those in the COMA BERENICES and PERSEUS constellations, have shaped our vision of the class of rich, populous, clusters. In this schematic view, rich clusters are smooth, round and virialized structures. This idealized picture coexisted with the knowledge that there are significant variations in the various properties of the Abell clusters. This has led to many studies of those properties, and of correlations between them, as well as to several attempts to describe the formation and evolution of rich clusters. It is now realized that clusters are still forming and evolving at the present epoch.

Among the cluster properties that can be studied, and for which theoretical predictions have been made are the 3D shape (or rather, the axial ratios of the galaxy distribution), the composition of the galaxy population (i.e. the fractions of galaxies of different morphological types), the distributions of the luminosities of the galaxies, the detailed dynamics of the various galaxy classes, dynamical substructure and segregation and the fraction of the total mass consisting of baryonic (i.e. 'ordinary' nucleonic) matter. An important recent development is the search for, and study of, galaxy clusters at very large distances (i.e. at high redshifts), which are the 'forebears' of the local rich clusters in the Abell catalogue. For those younger clusters at high redshifts, the Abell clusters serve as a local, present-day, reference population.

Abell clusters as a subset of the total cluster population

When searching for cluster candidates on the Palomar Sky Survey plates, Abell had no information about distances (or redshifts) of the galaxies. Therefore he used the distribution of the galaxies in apparent magnitude to select those peaks in the projected galaxy distribution that are most likely to correspond to a spatially compact structure. Taking the magnitude of the 10th brightest galaxy as an approximate 'standard candle', a redshift was estimated; this yields the angle subtended by a fixed linear size of $1.5h^{-1}$ Mpc at the distance of the cluster (where h is the value of the present Hubble parameter, expressed in units of 100 km s^{-1} Mpc^{-1}). In a circular aperture with radius equal to that angle, the number of galaxies with a magnitude not more than two magnitudes fainter than the third-brightest galaxy was counted. Finally, the number of unrelated galaxies in the aperture (and down to the same magnitude limit) was estimated from the galaxy density in background fields without obvious cluster candidates.

The corrected number of galaxies (the richness count, i.e. the estimated number of members in the aperture above the magnitude limit) was found to have an uncertainty of about 17. Therefore, only clusters with a corrected galaxy count of at least 50 were considered by Abell to have been sampled in an unbiased fashion out to redshifts of 0.1–0.2. In Abell's original ('northern') catalogue, 1682 of the 2712 cluster candidates have a count of at least 50. The lower limit in richness count must be applied if one uses the Abell catalogue for statistical purposes. Clearly, many less rich clusters exist but at larger distances–redshifts their contrast with respect to the field is too low to allow a robust definition of a statistically reliable sample.

In recent years, an extensive redshift survey (the ESO Nearby Abell Cluster Survey) has been made of close to 6000 galaxies in about 100 cluster candidates (mostly from the southern part of the Abell, Corwin and Olowin catalogue) with a richness count of at least 50 and estimated redshifts less than 0.1 (see GALAXY REDSHIFT SURVEYS). The contamination in these redshift surveys by galaxies that do not belong to the main cluster is far from negligible, i.e. about 25%. However, the majority of the redshift surveys contains a spatially compact cluster to which at least 50% of the galaxies with measured redshifts

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

belong. Only about 10% of the candidate clusters appear to be a superposition of two almost equally rich (but relatively poor) systems at different redshifts along the same line of sight.

For the spatially compact systems, the velocity dispersion shows a global correlation with richness count (clusters with higher richness counts on average have larger velocity dispersions), but the correlation is very broad (at least a factor of 2 in both quantities). The uncertainty in the visually estimated richness counts might be thought to be responsible for this, but the width of the relation does not decrease if one uses richness counts based on machine scanning instead of the original ones.

For a sample of about 150 Abell clusters with redshifts less than 0.15, cluster masses were calculated from the relative velocities and positions of the galaxies, assuming that the virial theorem holds in the central regions of the clusters. The cluster masses correlate fairly well with the velocity dispersions, but the mass distributions in the various intervals of richness counts appear to have considerable overlap. Therefore, application of a limit in richness count to a sample of Abell clusters (which is necessary for practical reasons) induces quite a diffuse limit in mass.

The clusters, or rather cluster candidates, in Abell's catalogue with richness counts of at least 50 are therefore a subset of all clusters in the mass range from about 4×10^{13} to $2 \times 10^{15} M_{\odot}$. However, for clusters with a velocity dispersion of at least 800 km s^{-1}, essentially all richness counts are larger than 50. In other words, all clusters with a velocity dispersion of at least 800 km s^{-1} are contained in the sample with a limiting count of 50, and the estimate of their space density is unbiased. Clusters with apparent velocity dispersions greater than about 1200 km s^{-1} turn out either to be superpositions or to have lots of dynamical substructure.

With the advent of all-sky x-ray surveys like those from the EINSTEIN (HEAO-2) and ROSAT missions, it has become possible to construct complete samples of clusters for which the x-ray flux from the hot gas in the potential well of the cluster is larger than a threshold value. This produces cluster catalogues that are fundamentally different from, and thus complementary to, the Abell catalogue, although there is quite some overlap. The mass of the x-ray gas is generally at least as large as the mass of the cluster galaxies, but the combined mass of these two baryonic components is typically only 10–15% of the total mass. When the total mass of a cluster can be estimated both from the kinematics of the galaxies and from the x-ray temperature and brightness, the two estimates in general agree reasonably well.

Properties of the galaxy population in Abell clusters

In the past, several schemes have been proposed for the classification of Abell clusters. All of them summarize in one way or another the distribution of the cluster galaxies in position, magnitude or morphological type, or any combination of those. The projected distribution of the galaxies has many forms and ranges between the following extremes. There may be a central concentration of bright galaxies, generally of early type, i.e. ellipticals, and frequently one of them is a cD galaxy, i.e. a giant elliptical surrounded by an extended envelope (see ELLIPTICAL GALAXIES). At the other extreme there are clusters that do not have a clear central concentration.

In some clusters, the galaxy distribution is quite smooth, and in general those clusters contain relatively few spiral galaxies. When the fraction of spiral galaxies is large, the galaxy distribution is in general less regular. The relative fractions of early- and late-type galaxies are correlated with richness count, and this is a manifestation of the morphology–density relation. The latter shows a clear correlation between the relative fractions of ellipticals, lenticulars (S0s) and spiral galaxies, and the (local) projected galaxy density (and therefore radial distance). The S0s may contribute up to 50% in the center, with ellipticals not far behind and spiral galaxies about 10%. In the outer parts, ellipticals are almost absent while spiral galaxies may represent up to 60%. Note that these are global values: individual clusters show a considerable spread around these.

Even though in a sizeable fraction of the Abell clusters the galaxy distribution is not very regular or circularly symmetric, one can always derive the azimuthally averaged projected number density profile $\Sigma(R)$, in which R is the projected distance from the cluster center, i.e. the shortest distance between the line of sight through a galaxy and the cluster center. Several expressions have been proposed for the mathematical description of $\Sigma(R)$, all of which have three parameters. Those are the central value of $\Sigma(R)$, i.e. $\Sigma(R = 0)$, a characteristic length R_c (the distance at which $\Sigma(R)$ has decreased by a given factor, say 2) and a measure of the decrease of $\Sigma(R)$ in the outer parts (generally the logarithmic slope α of $\Sigma(R)$).

Recently, $\Sigma(R)$ has been derived for galaxies of different morphological types in about 70 rich Abell clusters. In individual clusters, the number of galaxies of a particular type is generally not sufficient to allow an accurate estimate of the three parameters of $\Sigma(R)$. By properly combining data for many clusters one can compare the representations of $\Sigma(R)$ for ellipticals, S0s, spirals and galaxies with emission lines (mostly very 'late' spirals, such as Sc and Sd, with ionized gas in their interstellar medium). In other words, by sacrificing the detailed properties of individual clusters, one obtains a picture of an average rich Abell cluster.

There appears to be a clear correlation between galaxy type and $\Sigma(R)$: the characteristic length R_c increases markedly from early to late galaxy type (from about 0.1 to 0.5 Mpc). This shows that ellipticals are indeed much more centrally concentrated than spirals, while the emission-line galaxies form the most extended population. These differences must be accompanied by differences in the kinematics of galaxies of the various types, because all

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

galaxy classes move in the same cluster potential, which is mostly determined by the dark matter.

Such kinematical differences are indeed observed: the ellipticals and S0s show the smallest dispersion of the line-of-sight component of their velocities, and this dispersion varies little with projected distance from the center. Spirals, and in particular emission-line galaxies, have a larger velocity dispersion (by as much as 20–30%) which decreases markedly towards larger projected distances. Actually, the kinematics of the emission-line galaxies indicates that they have not yet traversed the dense central cores, which is probably the reason why they have not yet lost their line-emitting gas in encounters with other galaxies.

Combining the projected galaxy distributions with the kinematics one may estimate the distribution of the total (visible plus dark) mass via the Jeans equation of stellar dynamics. By comparing the distribution of the dark matter with that of the luminosity of the galaxies, one can in principle study the variation of the so-called mass-to-light ratio with distance from the cluster center. This may give clues about details of the formation process, such as the effects of galaxy encounters, the role of the dark matter haloes of the galaxies, etc.

Abell clusters as cosmological probes

Several observational properties of Abell clusters have been used to constrain the theories of formation of large-scale structure in the universe and the parameters in those theories (see also UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION). These properties include the spatial distribution of Abell clusters, their shapes and their masses. In different ways, these all carry information on the way in which the largest well-developed structures in the universe have formed through the growth of the initial fluctuations in the matter density.

The spatial distribution of Abell clusters has been analyzed through the two-point correlation function $\xi(r)$, i.e. the fraction of cluster pairs with a certain separation, in excess of the expected number of pairs for a random distribution, which has been derived for clusters of various richness counts. In general, the correlation function is found to have a power-law form: $\xi(r) = (r/r_0)^{-\gamma}$; the exponent γ (about 2) does not appear to depend on the limiting richness count, but the value of the correlation length r_0 does, and is larger for the richer clusters (with a characteristic value of about 20 Mpc). In principle, these data allow one to derive the value of the cosmological density as well as the amplitude of the fluctuation spectrum.

Another aspect of the distribution of rich Abell clusters is that they are generally located in the vertices where the sheets and filaments in the general galaxy distribution come together. Therefore, the distribution of rich clusters has sometimes been compared with the distribution of the vertices in so-called Voronoi tesselations, which are geometric partitionings of space.

The shapes of Abell clusters have been derived from the projected distributions of galaxies. Using the galaxy positions irrespective of galaxy type, one can calculate the apparent ellipticity of a cluster. In general, the richer clusters are less elongated than the less rich ones. The apparent ellipticities for a cluster sample of about 100 northern Abell clusters suggest that the elongated clusters are prolate (cigar like) rather than oblate. Comparison of these data with the results of numerical N-body calculations can constrain the theories of structure formation.

The full distribution of the masses of a volume-limited sample of Abell clusters (i.e. its shape *and* normalization) can also give information for cosmological structure formation theory. As the sample of Abell clusters with a limiting richness count of 50 has a rather badly defined completeness at smaller masses, one must restrict the comparison between observations and predictions to the most massive clusters for which the Abell catalog is complete.

It is far from trivial to derive independent information for the several parameters in the formation theories that influence the properties of the most massive structures. Yet, there seems to be general agreement that the latter are more naturally understood in a universe in which the matter density is considerably smaller than the critical density.

Aberration

(1) The apparent displacement of a star from its mean position on the celestial sphere due to the velocity of the Earth in its orbit around the Sun. The phenomenon was discovered in 1729 by James Bradley (1693–1762) who was, in fact, trying to measure stellar parallax. The displacement is caused by the combination of the velocity of the Earth and the velocity of light approaching from the source. If the Earth were stationary, light from a star would arrive from the true direction of this source, but the motion of the Earth causes the light to appear to be approaching from a point which is slightly displaced in the direction of the Earth's motion. In the course of a year, as the Earth travels round the Sun, a star will trace out a small ellipse in the sky about its mean position. The maximum radius of this ellipse (in radians) is equal to the ratio of the speed of the Earth to the speed of light (30 km s^{-1}:300 000 km s^{-1}), that is about 20.5 seconds of arc. The eccentricity of the ellipse depends on the celestial latitude of the star (the figure becomes a circle at the pole of the ecliptic and a straight line on the ecliptic).

The displacement due to aberration is much greater than that due to parallax (the annual parallax of the *nearest* star is 0.76 seconds of arc) and this must be allowed for before the parallax can be determined for a star. A similar, though smaller, aberration effect occurs due to the speed of rotation of the Earth on its axis. This is known as diurnal aberration.

(2) In optical systems, such as lenses and curved mirrors, aberration refers to the inability of the system to produce a perfect image. Unlike a plane mirror, which does not create aberrations, a lens or curved mirror is an imperfect image producer, becoming ideal only for rays passing through (or reflecting from) its center parallel to the optical axis (a line through the center, perpendicular to the lens surfaces). The main aberrations are chromatic, spherical, coma and astigmatism.

Abetti, Antonio (1846–1928) and Abetti, Giorgio (1882–1982)

Antonio was born in San Pietro di Gorizia, Italy. A civil engineer, he turned to astronomy and became director of the observatory in Arcetri and professor of astronomy at the University of Florence. His main interest was positional astronomy, observation of minor planets, comets and star occultations. In 1874 he observed the transit of Venus across the Sun's disk through a spectroscope. His son, Giorgio Abetti, was a solar physicist, born in Padova, Italy. He succeeded his father as director of the Arcetri Observatory. In the United States at Mount Wilson Observatory, he took up solar physics and, on his return to Italy, established a spectroheliograph in Arcetri, about 180 degrees in longitude away from Mount Wilson, to give nearly 24 h coverage of solar phenomena. Discovered the radial motion of gases in sunspots (*Evershed–Abetti* effect). He was well known as a popularizer of astronomy.

Absolute Zero

The lowest possible temperature; according to the kinetic theory of gases, this is the temperature at which all motion of atoms and molecules ceases. This temperature is equivalent to $-273.16\,^{\circ}\mathrm{C}$, and defines the zero of the kelvin, or absolute, temperature scale.

Absorption Spectrum

A pattern of dark lines or bands superimposed on a continuous spectrum. When a continuous spectrum of radiation (a broad range of wavelengths) passes through a material medium (for example, a cool, low-pressure gas), selective absorption occurs at certain particular wavelengths. This gives rise to a series of dips in intensity (absorption lines) which, in the visible region of the spectrum, appear as dark lines against the bright background of the 'rainbow' band of colors that comprises the continuous spectrum.

Photons of electromagnetic radiation may be absorbed through radiative excitation, a process that occurs when an electron in one of the lower energy levels of an atom or ion absorbs a photon with energy precisely equal to the difference in energy between that level and one of the higher permitted levels and, as a result, jumps (makes an 'upward transition') from the lower to the higher level. Because the energy of a photon is inversely proportional to wavelength, the larger the energy gap, the shorter the wavelength of the radiation that is absorbed when an electron makes a particular transition. An electron does not normally remain in an excited level for long (typically 10^{-8} s). When it drops down again, it emits a photon or photons that may or may not have the same wavelength as the one that was originally absorbed (depending on whether it drops directly to its original level or descends in a series of smaller steps). If it drops in a series of steps, each of which corresponds to the emission of a photon of lower energy (and longer wavelength) than the one that was originally absorbed, the total number of photons of the original energy will be reduced and the spectrum will be depleted at the input wavelength. Furthermore, although all the input photons were traveling along essentially the same direction (from the source to the observer), the re-emitted photons travel away in random directions. Consequently, far fewer photons at the absorption wavelength reach the observer than photons of other wavelengths. The resulting absorption line is darker than the adjacent part of the continuous spectrum but, because some photons of that wavelength do reach the observer, not totally black.

Because each permitted transition corresponds to absorbing light of one particular wavelength, atoms or ions of a particular element produce absorption lines at a number of different wavelengths, each chemical element having its own distinctive 'fingerprint' pattern of absorption lines. The shortest-wavelength lines correspond to the largest energy gaps (i.e. to transitions from the lowest, or 'ground', level of the atom or ion). If an electron absorbs a photon with energy in excess of the ionization energy (or 'ionization potential'), it will be removed from the atom. The absorption spectrum of a particular species of atom consists of several series of lines, corresponding to the various permitted transitions, the short-wavelength limit of the series corresponding to the photon energies above which ionization takes place. Because ionizing photons can, in principle, have any value of energy above the ionization energy, absorption can take place over a continuous range of wavelengths, shorter than the series limit. Absorption of this kind is called an absorption continuum.

The prominence ('strength') of any particular line depends on the number of atoms of the appropriate chemical element that have electrons residing in the energy level from which the relevant upward transition takes place (the degree of excitation). That, in turn, depends on the abundance of the particular chemical element (the relative proportion of that element in the absorbing substance) and on a number of other factors, in particular the temperature (the higher the temperature, the greater the proportion of electrons in excited states).

In addition to producing absorption through electronic transitions (like atoms and ions), molecules may also absorb (or emit) radiation by changing their states of vibration (their constituent atoms vibrate relative to each other) or rotation (a molecule, having a physical shape, can rotate about a particular axis). Molecular absorption spectra are complex, their various lines often merging into broader bands.

Abul Wafa Mohammad al-Buzjani (940–97)

Born in Buzjan, Nishapur (now Iran), Abul Wafa flourished as a mathematician and astronomer at the observatory at Sharaf al Daula, where he was the first to build a wall quadrant (over 6 m long) to observe star positions. Best known for trigonometry, he contributed to the theory of the Moon, in which he first used the tangent function, and introduced the secant and cosecant. The trigonometric tables that he calculated were 100 000 times more accurate than Ptolemy's.

Acceleration

Rate of change of velocity. This is expressed in units of meters per second per second (m s^{-2}), or other equivalent units. Thus, an acceleration of 10 m s^{-2} would imply an increase in velocity of 10 meters per second in one second.

See also: energy.

Accretion

The process by which a celestial body increases its mass by aggregating smaller objects which collide with it. Several types of object grow by accretion. In binary stars in which mass transfer is taking place, one member grows at the expense of the other; black holes, including supermassive black holes believed to be present in active galactic nuclei, also increase their mass by accretion. In both these cases matter is accumulated via an *accretion disk* orbiting the accreting object.

The process is particularly important in the formation of planets. Dust grains in a protoplanetary disk (or proplyd) around a young star collide and coalesce, gradually building up larger objects, which in turn collide and merge. Objects accreted in this initial phase of planet formation, while their sizes are in the range from millimeters to tens of kilometers, are termed planetesimals. Once an object's size is measurable in kilometers its own gravity becomes a factor in accretion. Collisional mergers between planetesimals allow larger bodies to be built up, and these are termed protoplanets, objects of a thousand kilometers or more. The subsequent evolution of protoplanets proceeds by mutual collisions of increasing violence, and the accretion of fragments produced in these collisions. The bodies left orbiting the star when this final phase of bombardment is over are termed planets.

Accretion Disks

By accretion one understands in astrophysics the accumulation of matter onto a heavy object, under the influence of its pull of gravity. The object can be, for example, a star, a black hole or a neutron star. Most of the objects of these types are quite isolated, without much gas around that could be pulled in by their gravity. Accordingly, the vast majority of stars do not show any evidence of accretion, while most neutron stars and black holes in our galaxy are unobservable for this reason.

While somewhat exotic compared with normal stars or galaxies, accretion disks attract attention because they are involved in a wide range of highly visible phenomena. These range from the formation of our planetary system and the rings of Saturn to the x-ray binaries in our galaxy and the collimated jets from protostars and accreting black holes.

The observable effects of accretion can range from modest to quite dramatic. This depends on the amount of mass accreted per unit time, but even more on the depth of the potential well of the gravitational field of the accreter. The simplest model of accretion would be a free particle falling radially to the accreter from a large distance. If it starts from rest at infinity, it arrives at the surface R of an accreter of mass M with the escape speed $v_e = (GM/R)^{1/2}$. We can also write this as $v_e/c = (r_g/2R)^{1/2}$, where $r_g = 2GM/c^2 = 2.8M/M_\odot$ km is the Schwarzschild radius of the mass M. For a neutron star with $M = 1.4M_\odot$ and $R = 10$ km, for example, the particle would arrive at the surface with some 30% of the speed of light. Accretion onto compact objects, in which M/R is large, is therefore accompanied by the release of large amounts of energy.

A free particle attracted to a compact object from a large distance has only a small chance of hitting it. If its initial motion is not directed very precisely to the object, it will just make an orbit around and return to the same large distance. In other words the cross section for accretion by free particles is small. The same effect plays a role when we consider the more realistic case of accretion of a gas and is then called the 'angular momentum problem', discussed below.

The accreting gas might, for example, be provided by a protostellar cloud, in the case of a growing protostar, or by a companion star in a binary. If the accreting star is a neutron star or black hole, such a binary is called an X-RAY BINARY; if it is a white dwarf, the binary is called a CATACLYSMIC BINARY. Finally, accretion of some form of interstellar matter onto a massive black hole in the nucleus of a galaxy produces an ACTIVE GALACTIC NUCLEUS (AGN).

Figure 1 shows an artist's impression of an accretion disk fed by mass overflow from the secondary in a binary. Images like this cannot be made with telescopes. Almost all disks are so small, as seen from Earth, that their geometry can be inferred only by indirect means. Disks that can be observed directly are our planetary system, the rings of Saturn and spiral galaxies. None of these, however, is typical for gaseous accretion disks. Our solar system is only the solid residue of an accretion disk that existed during its formation. In the case of Saturn's rings, the particles making up the rings also behave more like free particles than like a gas. The disks in spiral galaxies are much more complicated than gaseous disks. Also, galactic disks are not old enough to have accreted much onto the galactic core since their formation.

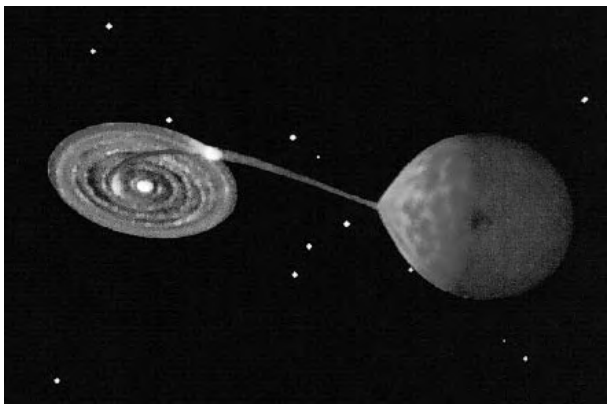

Figure 1. Artist's impression of a binary system consisting of a low-mass main sequence star (red) and a white dwarf. The main sequence star fills its Roche lobe and transfers mass to the white dwarf. Because of the orbital motion of the stars around each other, the mass-transferring stream of gas is not directed straight to the white dwarf and accumulates in an orbiting accretion disk. The impact of the stream on the disk edge causes a bright hot spot. (Copyright Dana Berry and Keith Horne, Space Telescope Science Institute.)

The best prospect for directly observing accretion disks is in protostars. They are the largest disks in angular diameter, as seen from Earth, and with currently developing high-resolution infrared and mm-wave imaging detailed observations of their structure will be possible (see INFRARED ASTRONOMY). Large 'proplyds' (protoplanetary disks) have been imaged in the optical by the Hubble Space Telescope; an example is shown in figure 4 of the article on YOUNG STELLAR OBJECTS.

In the case of binary systems like figure 1, information on the size, thickness and temperature of the disk is provided by eclipses. If the binary is oriented such that the Earth happens to be near its orbital plane, the disk and the mass-providing secondary star eclipse each other regularly as the components orbit around each other. The shape of the light curve in different wavelengths can then be used to infer the properties of the disk, such as its size and temperature (figure 2; see also BINARY STARS).

Accretion temperatures

A characteristic temperature in accretion problems is the virial temperature,

$$T_v = |\Phi|/\mathcal{R} \tag{1}$$

where $\mathcal{R} = 8.314 \times 10^7$ erg g^{-1} K^{-1} mol^{-1} is the molar gas constant and Φ the depth of the potential well. At

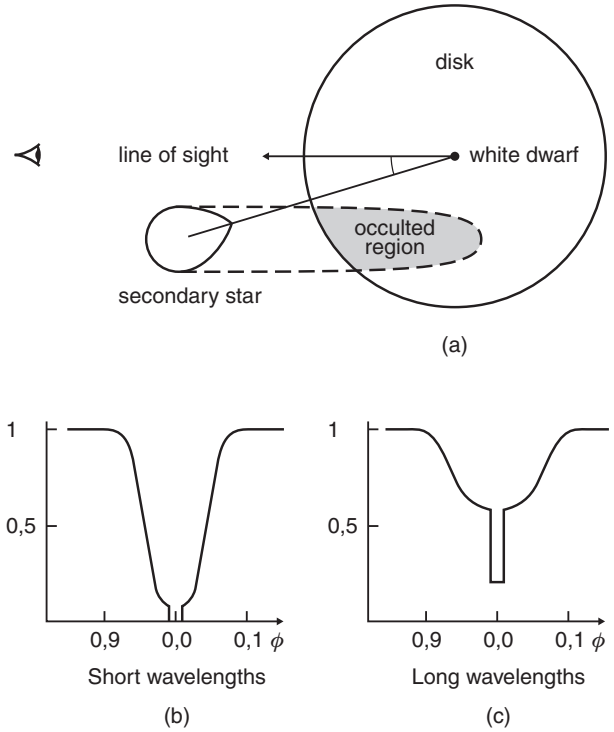

Figure 2. Light curve of an eclipsing binary with an accretion disk around the primary star. The accretion disk widens the eclipse of the primary star. Details of the light curve can be used to infer size and temperature of the disk. (Figure modified after Frank, King and Raine 1992 *Accretion Power in Astrophysics* (Cambridge: Cambridge University Press).)

a distance r from a point mass in Newtonian gravity, $\Phi = -GM/r$. If all the kinetic energy gained by dropping into the potential well were dissipated into internal energy (heat), the gas would reach a temperature of the order T_v. For a neutron star, $T_v \sim 2\times10^{12}$ K, corresponding to a mean thermal energy per proton of the order 1 GeV. The radiation actually observed from accreting systems indicates much lower temperatures. This is because a thermal plasma at this temperature radiates energy at an enormous rate, much higher than can be supplied by the infalling gas. Instead of T_v, the gas settles at a lower temperature, such that the dissipated energy is roughly balanced by energy lost by radiation.

A second characteristic temperature is obtained by assuming that the radiation is emitted as if by a black body from the surface of the accreting object. Equating the luminosity $L = 4\pi r^2\sigma T^4$ of a black body of radius R and temperature T_B to the energy generated by accretion at a rate $\dot{M}$ (mass per unit time) yields

$$T_B = \left(\frac{GM\dot{M}}{4\pi R^3\sigma}\right)^{1/4} \tag{2}$$

where $\sigma = 5.6692\times10^{-5}$ erg cm^{-2} K^{-4} s^{-1} is the constant in Stefan–Boltzmann's law. Actual temperatures differ from this, since the emitted spectrum differs from that of a black body, the emitting surface is not equal to that of the accreting object or, in the case of black holes, much of the accretion energy is swallowed by the hole rather than being radiated. Still, T_B often provides a good order of magnitude for the observed temperatures. The reason is that in these cases the accreting gas is optically thick, so that by repeated photon emission and absorption processes the accretion energy is reprocessed into something like a black body spectrum. For a cataclysmic variables, protostars and AGN, $T_B \sim 10^4$–10^5 K, for x-ray binaries around 10^7 K, corresponding to photon energies of 1–10 eV and 1 keV, respectively. Optically thin accretion processes can also occur, however (see below under 'Radiation processes, two-temperature accretion'), producing photons of much higher energies.

Radiation pressure and the Eddington limit

The photons released by an accreting object exert a force on the accreting gas. By scattering (or by absorption and reemission) on an atom, ion or electron, the outward direction of the photon is changed into a more random direction. The outward momentum of the photons is thereby transferred to the gas: the radiation exerts an outward force. If $F = L/4\pi r^2$ is the radiative energy flux at distance r, and κ the opacity of the gas (scattering plus absorption), the acceleration due to this force is $g_{rad} = F\kappa/c$. This force is just balanced by the inward acceleration of gravity $g = GM/r^2$ when the luminosity L has a value called the Eddington limit or Eddington luminosity:

$$L_E = 4\pi GMc/\kappa. \tag{3}$$

A steady photon source, bound by gravity, cannot have a luminosity significantly exceeding this limit. At a larger luminosity, the atmosphere of the source is blown off by radiation (this happens, for example in a NOVA explosion). The value of the Eddington luminosity depends on the opacity of the gas, and thereby on its state of ionization. It depends on the mass of the source but not its size. Close to the compact object in an x-ray binary the gas is nearly fully ionized, usually of normal stellar composition, and electron scattering the dominant radiation process, with opacity $\kappa \sim 0.3$ cm^2 g^{-1}. The Eddington limit is then

$$L_E \approx 1.5\times10^{38} M/M_\odot \text{ erg s}^{-1}. \tag{4}$$

For a neutron star of $1.4M_\odot$, this is about 50 000 times the luminosity of the Sun.

If this luminosity is generated by accretion, equating it to the accretion energy defines the Eddington accretion rate

$$\dot{M}_E = 4\pi cR/\kappa \tag{5}$$

or about $1.5\times10^{-8} M_\odot$ yr^{-1} for a neutron star of 10 km radius. A neutron star cannot accrete much more than this. The radiation pressure building up would prevent further accretion, and the gas would accumulate in an extended atmosphere around the star instead of settling

onto the neutron star surface. (This assumes that radiation is only by photons: at sufficiently high temperature and density energy losses by neutrinos become important.) The accretion rate onto a black hole can be much higher than $\dot{M}_{\rm E}$. An atmosphere surrounding a hole is not supported at its base, but flows in through the horizon. In the process it takes with it the photons trapped in the gas. Depending on the density of such an atmosphere, the accretion rate can be arbitrarily high. The luminosity as seen from Earth does not become much bigger than $L_{\rm E}$, however.

Disks

Mass transfer in a binary

As an example for the formation of an accretion disk, consider a binary in which one of the stars is large enough to fill its Roche lobe (see CLOSE BINARY STARS), the other being a compact star (white dwarf, neutron star or black hole). The Roche-lobe-filling star is called the secondary, since it is the less massive star in such binaries. Mass flows off the secondary at the inner Lagrange point L_1. The orbit of a hypothetical free particle from this point is shown in figure 3. Except directly at L_1, the orbital velocity is very high compared with the sound speed of the gas. Consequently, its path is almost ballistic, i.e. close to that of a free particle. Since gas clouds cannot flow through each other, however, the ballistic flow ceases at the first intersection point of the orbit. The supersonic relative motion of the two parts of the gas stream is dissipated here through shock waves, heating the gas and deflecting the stream.

The further evolution of the stream depends on additional physics such as the rate at which the gas can cool. An example of what the stream might look like after a few orbital periods of the binary is shown in figure 4. The orbiting gas has accumulated into a ring; newly arriving gas is incorporated into the ring through a system of shock waves. The strongly non-circular motion of the gas has settled into a more quiet circular orbit; most of the energy dissipated in the process has been radiated away. Leaving aside perturbations by the impacting stream, and in the absence of viscous forces, the gas can orbit indefinitely on such circular orbits.

The 'angular momentum problem'

In the process of settling onto a circular orbit, a great deal of energy is dissipated, but the angular momentum of the gas around the primary has not changed (neglecting corrections due to the gravitational pull of the secondary). Since a circular orbit has the lowest energy for a given angular momentum, the gas can only sink further into the gravitational potential and accrete onto the primary, if it can lose some angular momentum. Finding the process by which this is done in real systems is called the angular momentum problem. We have illustrated it here with the example of mass transfer in a binary, but the same problem arises for the formation of stars from interstellar clouds or the accretion of gas onto the massive black holes in AGN. In these cases, the initial angular momentum due to random motion of the gas clouds is many orders of magnitude larger than can be accommodated by the accreting object. Rather than accreting directly, the gas forms a disk, acting like a temporary 'parking orbit'. The orientation of the disk is given by the direction of the total angular momentum vector of the clouds, while the time it takes the gas to spiral in through the disk depends on the processes solving the angular momentum problem.

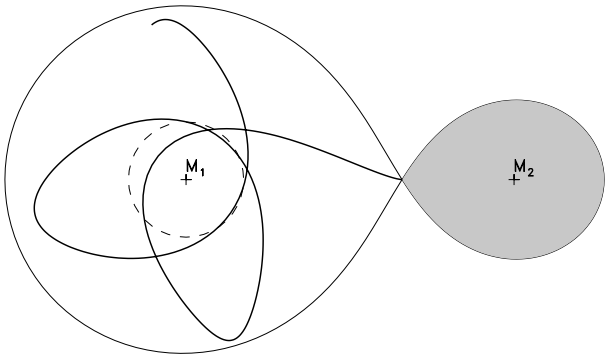

Figure 3. Binary showing Roche lobes, the lobe-filling secondary star (M_2, hatched) and the orbit of a particle released from the inner Lagrange point. The 'rosette' shape of the orbits around the primary (M_1) is caused by the orbital motion of the binary.

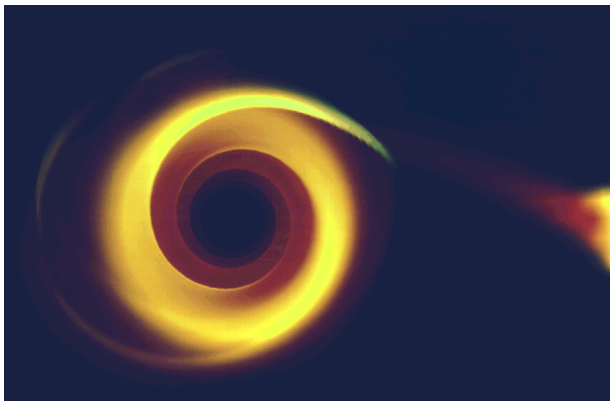

Figure 4. Hydrodynamic simulation of mass transfer in a binary, showing the accumulation of gas in a ring. An additional viscous process has to be added to make the gas accrete onto the primary star (at the center of the ring).

Viscous disks

In many cases (dwarf novae and x-ray transients; see X-RAY BINARY STARS) the accretion onto the compact object is episodic, in the form of outbursts. The decay of such an outburst gives some information on the accretion time, that is, the time it takes the gas to spiral in from the secondary star to the accreting primary. For dwarf novae, for example, this time is a few days, showing that the angular momentum transport process allows accretion in a few days or less of the mass that is involved in

producing the outburst. Though actual numbers are model dependent, these observations indicate angular momentum transport 12–15 orders of magnitude more efficient than expected from the natural viscosity of the gas. The process responsible for the angular momentum transport in disks is not known with certainty. In view of this uncertainty, the theory of accretion disks makes an arbitrary assumption about the angular momentum transport process. It is assumed that the disk behaves, in effect, like a fluid with a very high viscosity.

Such an enhanced viscosity does indeed solve the angular momentum problem. As a thought experiment, start with a ring of gas orbiting at some distance from the source of the gravitational potential. Viscous stress between neighboring orbits rotating at slightly different velocity makes the ring spread both outward and inward, forming a disk. This spreading has a remarkable property: if sufficient time is available, almost all the mass accretes onto the central object. A small amount of mass in the the outer parts of the disk expands indefinitely, carrying away almost all the angular momentum of the original ring. The time for spreading to a given distance is inversely proportional to the viscosity.

A characteristic velocity in the disk is the isothermal sound speed $c_s = (\mathcal{R}T)^{1/2}$, where T is the temperature at the midplane of the disk (the surfaces are cooler). A characteristic frequency is the orbital frequency Ω. The unknown disk viscosity ν can then be measured in terms of a dimensionless viscosity α, defined by

$$\nu = \alpha c_s^2/\Omega. \tag{6}$$

Where observational indications, such as the decay time of an outburst, are available, they indicate viscosities in the range $\alpha = 10^{-3}$–1. Such values are then used when making theoretical estimates of the structure of accretion disks. The assumption that the angular momentum transport processes can be represented by equation (6), with α something of order unity, is called the α-viscosity assumption.

Thin disks

Accretion disks tend to be cool because the accretion times are long and sufficient time is available to radiate away the dissipated gravitational energy. If they are cool, the effects of gas pressure are small. To see this consider the equation of motion for an ideal gas in a gravitational potential of a point mass M, $\Phi = -GM/r$:

$$\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = -\frac{1}{\rho}\boldsymbol{\nabla} p - \nabla\Phi \tag{7}$$

where $\boldsymbol{v}$ is the velocity, ρ the mass density and p the gas pressure. At a distance r_0, a characteristic time scale t_0 is the inverse of the Kepler frequency, $t_0 = \Omega^{-1} = (r_0^3/GM)^{1/2}$. Introducing dimensionless quantities $t' = t/t_0$, $r' = r/r_0$, $\boldsymbol{\nabla}' = r_0\boldsymbol{\nabla}$, $\boldsymbol{v}' = \boldsymbol{v}/\Omega r_0$, the equation of motion for a gas of temperature T becomes

$$\frac{\mathrm{d}\boldsymbol{v}'}{\mathrm{d}t'} = -\frac{T}{T_v}\boldsymbol{\nabla}' \ln p - \frac{\hat{\boldsymbol{r}}}{r'^2} \tag{8}$$

where $\hat{\boldsymbol{r}}$ is a unit vector in the radial direction and T_v the virial temperature introduced above. For processes taking place on a length scale r_0 and time scale t_0 the terms in this equation are of order unity, except the pressure term which involves the factor T/T_v. T/T_v is of order unity if all the dissipated energy stays in the gas, but, when cooling is effective, it can be very small. The pressure term is then small, and the gas flows ballistically in the potential Φ.

A disk with $T/T_v \ll 1$ rotates approximately on circular Kepler orbits. The orbital motion is supersonic, with Mach number $\mathcal{M} = \Omega r/c_s \sim (T_v/T)^{1/2}$. The thickness of the disk is found by considering the vertical distribution of gas at some distance r_0, assuming it to be in hydrostatic equilibrium in a frame rotating with the Keplerian rate $\Omega(r_0)$. An isothermal gas is then distributed with height z above the orbital plane as $\rho \sim \exp[-\frac{1}{2}(z/H)^2]$, where H is the scale height, $H = r_0(T/T_v)^{1/2} = c_s/\Omega$. If radiative losses are small, the disk is hot, and the aspect ratio H/r_0 is of order unity. Efficiently radiating disks on the other hand are cool and geometrically thin, $H/r \ll 1$.

Under the assumption $H/r \ll 1$ the hydrodynamic equations for an axisymmetric, plane, viscous disk are simple. To lowest order, the radial equation of motion reduces to $v_\phi = \Omega r$. The azimuthal equation of motion can be combined with the continuity equation into a single equation governing the surface density $\Sigma = \int_{-\infty}^{\infty} \rho \, \mathrm{d}z$:

$$\frac{\partial \Sigma}{\partial t} = \frac{3}{r}\frac{\partial}{\partial r}\left[r^{1/2}\frac{\partial}{\partial r}(\nu\Sigma r^{1/2})\right]. \tag{9}$$

As expected, this equation is of the diffusion type. It shows that, for a cool disk, all physical factors influencing the evolution of the disk enter only through the viscosity ν. This viscosity, of course, also contains most of the assumptions about unknown processes. Usually, additional equations are needed to determine how radiative cooling affects the temperature structure of the disk, on which ν depends.

For steady accretion, and not too close to the central object, the accretion rate is related to the viscosity by

$$\dot{M} \approx 3\pi\nu\Sigma. \tag{10}$$

A high viscosity implies a low surface density, since the accreting mass spends little time in the disk. The characteristic time t_a for gas orbiting at a distance r to accrete is the viscous time scale,

$$t_a = r^2/\nu \approx \frac{r^2}{H^2}\frac{1}{\alpha\Omega}. \tag{11}$$

For cool disks, this is long compared with the orbital time scale. On the other hand, a long time scale implies that there is plenty of time for the disk to cool by radiation, so there is a certain circularity in the mechanism that fixes the disk temperature. In a given situation (central mass, distance), the disk temperature is determined by the mass accretion rate and the dominant cooling process. In some cases, disks can exist in either of two stable steadily

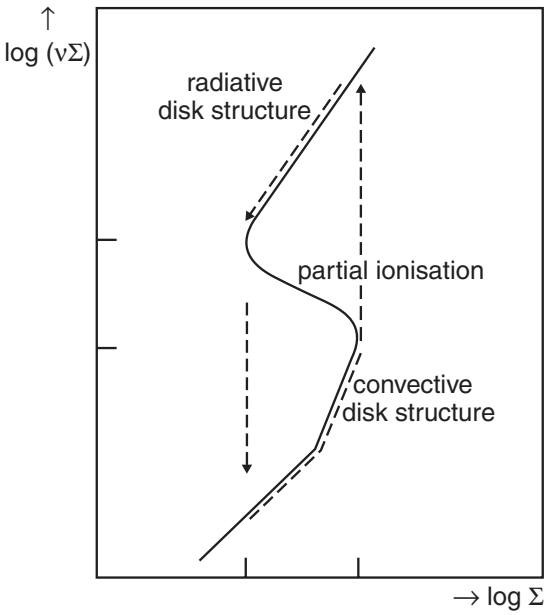

Figure 5. Dependence of the viscous stress $\nu\Sigma$ on surface mass density Σ in a disk where hydrogen is partially ionized. If the mean accretion rate requires a viscous stress in the range where the slope of the curve is negative, this part of the disk is unstable and executes a limit cycle as sketched by the arrows.

accreting states, a cool one with long accretion times and a hot one with short accretion times. In other cases, disk models are found to be unstable for certain mass transfer rates, oscillating between states of high and low accretion. The details of the cooling processes determine when such multiple accretion states exist (see 'Radiation processes, two-temperature accretion' below).

Disk instabilities

The vertical structure of a disk is determined by the need to transport the viscously dissipated energy to the radiating surfaces. For a given surface density Σ, this structure determines the temperature and viscosity of the disk. In conditions where the energy transport process changes rapidly with temperature, the viscous stress $\nu\Sigma$ can depend non-monotically on the surface mass density, in the form of an 'S-curve', as illustrated in figure 5. If the mean accretion rate which is imposed (for example, by the mass-transfering secondary star) lies in the range where Σ decreases with increasing $\nu\Sigma$ (cf equation (10)), the disk is unstable. Instead of accreting steadily, it executes a limit cycle alternating between states of high and low accretion. Usually, conditions like those in figure 5 occur only in limited regions of the disk, for example in the region of partial ionization of hydrogen. If this region contains enough mass, however, the limit cycle will affect the entire disk. This is believed to be the cause of the dwarf nova outbursts in cataclysmic variables.

Angular momentum transport processes

Historically, the idea that some form of hydrodynamic turbulence exists in disks has played a significant role. It was part already of the ideas of Kant and of Laplace, who proposed that the solar system was formed from an initially gaseous disk-like cloud. If $\nu_{\rm m}$ is the microscopic viscosity of the gas, the Reynolds number $r^2\Omega/\nu_{\rm m}$ in an accretion disk is very large, a situation called 'fiercely turbulent' in fluid mechanics (where high Reynolds numbers and turbulence are considered equivalent). The assumption is that the shear flow in a disk would be unstable and develop into turbulence, as in laboratory shear flows. This has been questioned in the astrophysical community, on account of the fact that the flow in a cool disk is close to Kepler orbits, which are very stable. At the time of writing, the issue is still controversial, but it seems quite possible that a Keplerian gas flow does not, in fact, produce hydrodynamic turbulence. A closely analogous laboratory case is the rotating Couette flow. Significantly, this experiment has not shown turbulence for the conditions corresponding to an accretion disk, in which the rotation frequency decreases with distance but the specific angular momentum increases (although turbulence abounds for other parameter values). Attempts to demonstrate turbulence for this case by analytical studies or numerical simulations of the experiment have also been negative.

Among the processes known to work are spiral shock waves. In a large disk (in the sense that the outer radius is much larger than the inner radius), a small compressive perturbation propagating inward steepens into a weak shock wave. Dissipation in the shock damps the wave, but since it also propagates into a flow of increasing velocity, the interaction between wave and mean flow though the shock increases its amplitude. In the absence of other processes damping the wave, a shock of finite strength develops by the balance between shock dissipation and energy extraction from the mean flow. The process produces a modest amount of angular momentum transport, corresponding to $\alpha = 0.01(H/r)^{3/2}$. For protostellar disks, this is in the range of the values inferred from observations, but it is too low for cataclysmic variables and x-ray binaries.

If the disk is massive enough that self-gravity is important, angular momentum transport by gravitational instability is possible. The intrinsic growth rate of a gravitational instability is of the order $(2\pi G\rho)^{1/2}$. If this is larger than the shear rate $\sim\Omega$, instability can grow in a disk; if it is smaller, a prospective perturbation is sheared apart before it can grow. In terms of a characteristic disk mass $M_{\rm d} = 2\pi r^2\rho H$, this condition can be written as $M_{\rm d} > MH/r$. Such disks are called self-gravitating. Self-gravity is more important in cool disks, with small aspect ratio H/r. With the viscosities assumed, the masses of disks in observed systems can be estimated. For x-ray binaries and cataclysmic variables they turn out to be quite small, less than $10^{-8}M_\odot$, and self-gravity is unimportant.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

In the outer parts of disks in AGN, and in particular in protostellar disks, on the other hand, self-gravity can be important (see YOUNG STELLAR OBJECTS). In this case, consider a disk cooling by radiation so that H/r decreases with time. As the threshold for instability is reached, non-axisymmetric irregularities with length scales of the order H are formed, which exert forces on each other. The shear flow acting on these forces dissipates energy, which in turn heats the disk. A balance is reached at a temperature just above the threshold for gravitational instability, and angular momentum is transported by the gravitational and pressure forces between the perturbations. This process is likely to be important in young protostellar disks, with inferred masses of the order of a few per cent of a solar mass (see STAR FORMATION).

The currently favorite process for non-self-gravitating disks relies on the fact that most disks are partially or fully ionized and hence support magnetic fields (see MAGNETOHYDRODYNAMICS). The possibility that the actual angular momentum transport in disks is done by some form of small-scale magnetic field has already been proposed by Shakura and Sunyaev together with their introduction of the α-viscosity assumption. It can be shown that an initially weak magnetic field in an accretion disk is unstable, its energy density growing by extracting energy from the shear flow. The mathematics of the process was computed around 1960 by Velikhov and by Chandrasekhar, its physical interpretation given by Fricke in 1972 and its importance for accretion disks finally realized by Balbus and Hawley in 1992. Numerous three-dimensional numerical simulations since then have shown how this instability gives rise to the magnetic turbulence postulated earlier. For sufficiently ionized disks the process yields an effective viscosity $\alpha \sim 0.1$. It is a small-scale magnetic field, with length scales in the radial direction of the order of the disk thickness H, and appears to behave roughly as expected from a viscous process. The magnetic field appears to break the dynamic constraints that prevent a Keplerian flow from becoming turbulent by purely hydrodynamic means. In some respects the process resembles the hydrodynamic turbulence proposed earlier, but differs in important aspects as well. The angular momentum transport, for example, is dominated by the magnetic (Maxwell) stresses rather than by fluid motions.

Planets inside disks

Planets grow from a protostellar disk at the same time as the star is formed (see SOLAR SYSTEM: FORMATION). A planet like Jupiter is massive enough to significantly affect the dynamics of this disk. By its tidal effect it clears a gap, a region of low gas density around its orbit, as shown in figure 6. The tidal force excites waves in the disk which propagate away from the planet. Through the tidal forces, the planet attracts gas from the sides of the gap which accretes onto it in the form of two streams. On the other hand, the disk also exerts a gravitational torque on the planet. By this force, the planet's angular momentum changes. It moves to a different orbit, usually closer to the star. The planets in our solar system are therefore probably not at the distances where their formation started. An extreme example of this 'drifting planet' process may be the massive planets observed in very tight orbits around some nearby stars (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS).

Radiation processes, two-temperature accretion

The radiation produced by a disk depends on its optical thickness τ. The energy released in the disk by viscous dissipation, per unit surface area and time, at a distance r from the central mass M is of the order $W = GM\dot{M}/r^3$. This heat diffuses out by radiation. If τ (more precisely, the optical thickness for absorption processes) is large, the radiation emitted at the surface is roughly a black-body spectrum. The approximate surface temperature T_s of a cool optically thick disk is then given by equation (2), with R replaced by the distance r.

If the accretion is steady, so that $\dot{M}$ is independent of r, the predicted temperature varies as $r^{-3/4}$. In the case of protostellar disks and disks in cataclysmic variables, these temperatures are similar to those of normal stellar surfaces, and the same radiation processes determine the details of the emitted spectrum. In accreting black holes and neutron stars, the predicted temperatures are of the order 1 keV (10^7 K). Indeed, the x-ray spectra of these objects often show a component that agrees with this prediction. Usually, however, there is an additional hard component of much more energetic photons, around 100 keV. It often dominates the radiated energy. In these binaries there is an additional component in the accreting plasma that behaves differently from an optically thick disk. The precise nature of this plasma is one of the classical problems of x-ray astronomy, which at the time of writing has not been solved entirely. From the observed spectrum, it appears to be a thermal plasma of modest optical thickness ($\tau \sim 1$) and a temperature around 100 keV, much hotter than the cool disk. The main process producing hard photons under such conditions is inverse Compton scattering of soft photons by hot electrons.

In the neighborhood of black holes and neutron stars accretion is possible not only via a cool optically thick disk. Theory also predicts the possibility of accretion via a hot state (cf discussion above under 'Thin disks'). In this state, the protons are near the virial temperature, while the electrons are much cooler. The accretion flow is geometrically thick ($H/r \sim 1$) but optically thin. Under these conditions, the Coulomb interactions between ions and electrons can be slow compared with the accretion time (depending on accretion rate and viscosity parameter). Since the electrons radiate much more effectively, and are inefficiently heated by the ions, they remain much cooler than the ions: the accretion plasma is not in thermal equilibrium. The Coulomb interaction rate decreases with increasing electron temperature while radiation losses by inverse Compton and synchrotron radiation increase. In a flow of modest optical depth, the inverse Compton losses increase exponentially above

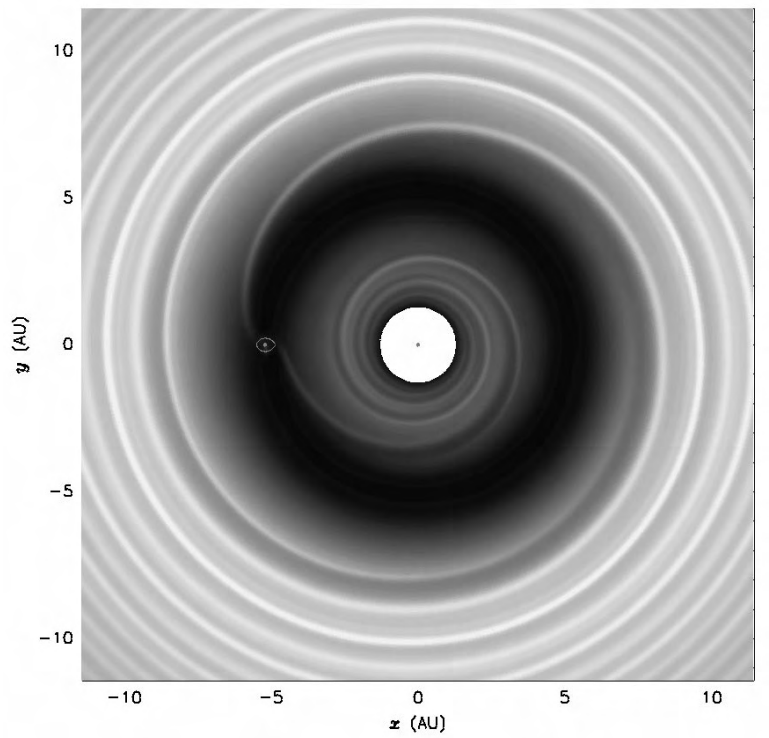

Figure 6. Numerical simulation of a growing gaseous planet inside the protoplanetary disk. The planet has cleared a gap in the disk and accretes gas from the sides of this gap. (W Kley, Institute for Theoretical Physics, University of Jena.)

about 100 keV, so that this a somewhat natural temperature to expect for the emitted radiation. The possibility of such a two-temperature accretion flow to explain the hard spectra of x-ray binaries has already been proposed in the beginning of the x-ray astronomy era. The geometry of such a flow and the nature of its interaction with the cool disk component are still uncertain, however.

Jets from disks

Most systems with accretion disks appear able to produce strongly collimated outflows called jets, at least at some periods in their existence (see ASTROPHYSICAL JETS). Jets with relativistic flow speeds are known from accreting black holes, both the stellar mass holes in x-ray binaries and the massive holes in AGN. Jets at more modest speeds are produced by protostars. They are also known from at least one accreting neutron star (Cir X-1) and an accreting white dwarf (R Aqr). The connection between disks and jets is thus suggestive, but at the same time puzzling. Although jets always seem to be associated with accreting systems in which there is direct or indirect evidence for a disk, not all systems with disks produce jets, or not all the time. A good example are the HERBIG–HARO OBJECTS produced by jets from protostars, which clearly demonstrate that the jets in this case are episodic or highly variable in time (see also PRE-MAIN SEQUENCE STARS).

Summary of types of disk

On a stellar scale, disks are produced in binaries by overflow of gas from one of the components onto the other. The sizes of these disks are as large as normal stars, from a few tenths to a few solar radii. If the primary (the mass-receiving star) is a white dwarf, such as in cataclysmic variables, the inner parts of the disk radiate mostly in the UV, the outer parts in visible light. The mass transfer through these disks is often unstable, causing dwarf nova outbursts. If the primary is a neutron star or stellar-mass black hole, the inner disk radiates in x-rays. Mass transfer in these disks is also unstable at low transfer rates, causing the so-called soft x-ray transients. They sometimes produce jets at relativistic speeds. Disks around stars in the process of formation, the protostellar disks (also called PROTOPLANETARY DISKS), are much larger (around 100 AU). Their inner regions radiate in the visible, the outer parts at infrared to radio wavengths. They are probably also unstable, causing the FU Ori outbursts, and are associated with jets and Herbig–Haro objects. Disks in AGN rotate around massive ($(10^6$–$10^9)M_\odot$) black holes at the centers of active galaxies. Their central regions radiate both in the UV and in x-rays and often produce the relativistic jets seen in double-lobed radio sources. Their sizes are somewhat uncertain, but probably of the order of a parsec or larger.

Disks are also seen around BE STARS. The mass in these disks is believed to be slowly expelled by the rapidly

rotating star. Some of their properties are similar to those of accretion disks, but with mass drifting away rather than accreting onto the star. They are sometimes called excretion or decretion disks.

Ace (Advanced Composition Explorer)

NASA mission to study the solar corona, interplanetary medium, solar wind and cosmic rays. Launched August 1997 and placed in a halo orbit at the L1 Lagrangian point between Earth and Sun. It carries six high-resolution spectrometers and three monitoring instruments with a collecting power 10 to 1000 times greater than past or planned experiments. Its mission is to sample low-energy particles of solar origin and high-energy galactic particles. (See also EXPLORER.)

Achernar

The star α Eridani, at the mouth of the great river depicted in ancient star maps. It is a bluish-white main-sequence star, spectral type B3Vp, and at apparent magnitude 0.45 is the ninth brightest star in the heavens. It is at a distance of 142 light-years, and has a parallax of 0.023″. Its absolute magnitude is −2.7.

Achilles

The first Trojan asteroid to be discovered, by Max Wolf in 1906, designated (588) Achilles. It belongs to the largest group of Trojans, orbiting ahead of Jupiter around the L_4 Lagrangian point. It has an estimated diameter of 147 km, and orbits the Sun at a mean distance of 5.17 AU (774 million km) in a period of 11.78 years. The inclination is 10° and the eccentricity 0.15. Like the majority of Trojans, Achilles is D-type, with a reddish reflectance spectrum indicating a carbon-rich surface.

Achondrite

One of the two main divisions of stony meteorites, the other being *chondrites*. Unlike the chondrites, the achondrites lack chondrules—millimeter-sized grains of silicate—and have a coarser crystalline structure than the chondrites. They contain almost no nickel–iron or sulfide. Achondrites are classified principally by their calcium content. The main calcium-rich (about 5%) varieties are the *eucrites* and *howardites*; the main calcium-poor (1% or less) types are the *aubrites*, *diogenites* and *ureilites*. Howardites, eucrites and diogenites are known collectively as *HED meteorites* or *basaltic achondrites*. The basaltic achondrites have all the characteristics of igneous terrestrial rocks, such as basalt, that were once molten, and are therefore inferred to be fragments from the crust of a parent body that underwent at least partial differentiation; the prime candidate is the Asteroid (4) Vesta. The largest known single achondritic mass is a 1 tonne fragment of the Norton County (Kansas, 1948) meteorite. Into this category also fall all known lunar meteorites, whose composition is consistent with them having been ejected from the surface of the Moon by impact, and all of the SNC meteorites, believed to have been ejected from the surface of Mars.

Compare: Chondrites.

See also: SNC meteorite, Vesta.

Acousto-Optic Spectrographs

The acousto-optic spectrograph (AOS) has played an interesting niche role in radio astronomical observation. By using the interaction between a laser beam and an ultrasonic vibration generated from the incoming radio signal, the AOS makes possible sensitive, wide-band observations of radio phenomena which vary in both frequency and time. This has been especially true in observations of solar radio emissions and in wide-band spectral line observations as found at millimeter wavelengths. Extensions of the technique have been applied to radio antenna arrays as an alternative signal processing technique to the use of high-speed digital electronics. However, the inherently analog nature of the instrument along with the enormous advances in digital technology have reduced progressively those areas of application where the AOS has a distinct advantage over purely digital approaches. Nevertheless, the simplicity, compactness and a capacity to process a thousand or more resolution channels over a radio bandwidth of a gigahertz or more continue to make the AOS a useful instrument in MILLIMETER and INFRARED ASTRONOMY for both ground-based and space-based observations.

The core component of the AOS is the ultrasonic delay line in which a piezoelectric transducer bonded to an acoustic transmission medium converts the applied electrical signal into a travelling ultrasonic acoustic wave in the form of progressive wavefronts and troughs of increased and decreased material density. In a typical crystal medium where the acoustic velocity is of order 3 mm μs^{-1}, it is quite feasible to achieve (along a 30 mm length of medium) a 10 μs sample of the incoming signal. Through polished faces to the medium, this can be probed with an applied laser beam which has been expanded and collimated. The density variations are, in effect, an optical phase grating and cause scattering of the light. This is the acousto-optic interaction in which light is scattered at an angle from the applied light. The sine of this angle is directly proportional to the frequency of the applied radio signal. In the limit of small angles and small scattered light, energy at the various frequencies within the applied radio signal will produce a proportional amount of optical energy at angles proportional to the frequency. A lens is used to focus the scattered light onto an integrating, one-dimensional solid-state photodiode array for read-out to a computer or a display or for recording on a moving piece of film. That is, the one-dimensional distribution of light intensity is an optical representation of the power spectrum of the applied radio signal. The limit to resolution of two closely spaced spectral features is then the inverse of the interaction length which, in this example of a 10 μs system, would be of order 100 kHz.

The technique was first described by Lambert [1] in 1962 and first applied to RADIO ASTRONOMY in 1966 at CSIRO in Australia by Cole [2] using a water acousto-optic medium, with a 1 MHz bandwidth and by recording through a slit onto continuously moving film. It was reported to the 1966 URSI conference in Munich. An improved instrument using a fused silica medium giving 800 resolution cells over a 100 MHz bandwidth was reported in 1973 [3] which produced radio spectra of solar burst activity and led to various instruments being built for solar and Jupiter time-resolved radio emission spectroscopy. These were at observatories in the Soviet Union, Finland, China, Japan and Australia.

Progressive improvements to the AOS included better acoustic impedance matching between the transducer and medium in order to increase the fractional bandwidth of the interaction and the use of solid-crystal acousto-optic media such as lithium niobate, lithium tantalate and lead molybdate to improve the efficiency and spectral range over which the spectrograph would work.

However, it was the development of the one-dimensional solid-state photodiode array and the micro-computer which provided the improvements needed for accurate astronomical spectral line observations. By integrating the light onto the photodiodes and by use of calibration, it became possible to use the computer to integrate and subtract background in order to observe weak spectral lines. Although this was first demonstrated by adding a photodiode array to the existing solar instrument [4], the first serious AOS spectral line applications were carried out with the Parkes radio telescope in 1977 [5].

The clear advantages of the AOS in simplicity, spectral range and number of channels were apparent and resulted in a number of observatories in Japan, France, Germany and Australia constructing AOSs. As the bandwidth and channel capacity of the transducers and available photodiode arrays grew, the instruments became focused more and more on the challenges of millimeter wavelength spectral line observations.

However, other, unique results were obtained with the AOS. The capacity to obtain high-time-resolution and frequency-resolution spectra over wide bandwidths revealed very clearly the structure of interplanetary SCINTILLATION phenomena previously only interpreted from observations taken at widely spaced, discrete frequencies [6]. Similarly, much detail was revealed in real-time and very wide fractional bandwidth observations of PULSAR SIGNALS [7]. Such observations revealed in a very graphic way the complex phenomena of pulsar signals including interstellar dispersion, Faraday rotation and scintillation.

Extension of the technique to the processing of RADIO INTERFEROMETER data becomes possible by a number of techniques which would include construction of a series of acoustic beams displaced in an analogous manner to the radio antennas along a one-dimensional antenna array. In this case the optics can display a two-dimensional image of the spectrum as before but, orthogonally, radio spatial image data. However, although demonstrated in principle, the inherently analog nature of the technique has not been able to achieve the extremely high dynamic ranges now required in radio astronomical imaging and able to be achieved with digital processing techniques.

The usefulness of the AOS therefore becomes apparent as observations move into the sub-millimeter and infrared spectral ranges where the spectral details require very wide spectral coverage combined with a large number of resolution channels. Digital circuitry does not currently operate at such speeds and any digital solution becomes bulky and consumes significant power. Both of these commodities are scarce on the spacecraft needed to take the observing instrument above the Earth's absorbing atmosphere.

The AOS therefore continues to form a useful niche technique within radio astronomical observation. It provides access to a range of frequencies, resolution and channel number not easily possible by other techniques. However, the inexorable progress of digital techniques has restricted progressively the area of its unique advantage to the more exotic fields of space, millimeter and infrared astronomy.

Active Galactic Nuclei: Variability

Variability studies have been essential in understanding the physics of ACTIVE GALACTIC NUCLEI, AGN, because the size of the region emitting the enormous amount of energy characteristic of AGN is too small to be resolved even with existing or planned optical/infrared (IR) INTERFEROMETERS.

AGN emit a continuum radiation coming from the vicinity of the BLACK HOLE. They also emit intense and broad emission lines originating in fast-moving gas clouds located in a small region around the continuum source: the broad line region or BLR.

The flux level of the continuum and the intensity of the spectral emission lines emitted by AGN undergo variations on timescales ranging from hours to years depending on the energy range and on the intrinsic luminosity of the AGN.

When the flux emitted by a source of energy varies significantly (say by a factor of 2) with a timescale t this flux variation sets a limit to the size R of the emitting region such that $R \leq ct$. In AGN the combination of the enormous amount of energy emitted and the very small size of the emission regions set by the short variability timescale is not compatible with the energy being produced by normal stellar processes. The most popular model for the energy production in AGN and the basis of the current paradigm is that AGN/quasars are powered by accretion of matter onto a SUPERMASSIVE BLACK HOLE.

At higher photon energies, more rapid and higher amplitude variability is observed, e.g. the x-rays vary more than the optical (figure 1). The variability timescales tend to be longer in intrinsically brighter objects. The timescales and the correlations and delays between the variations of the continuum flux and of the various spectral line intensities provide information on the nature of the physical processes emitting the lines and the continuum, and on the location of the regions from which they originate.

The term AGN is used here regardless of redshift and luminosity and therefore encompasses the terms Seyfert 1 and QSO or quasar, which are often used to designate medium- and high-luminosity AGN separately. In general, there are more data and of higher quality available for Seyfert 1s than for quasars. The reason is that they are numerous and quite a few are located within 100 Mpc of the Earth and are easily observable with the current instrumentation. In contrast, quasars are rare and even the closest ones are at such large distances from us that the flux received on Earth is much less than that from Seyfert 1s (there is one exception, 3C 273). In summary, the body of knowledge of AGN variability is dominated by the observations of Seyfert 1s, which have led to physical models which satisfactorily explain the observed phenomena. It remains to be investigated how these models apply to much brighter and to much fainter AGN.

The AGN that are the subject of this article are those in which the central optical, UV, and x-ray source is viewed directly and where the variations are not amplified by relativistic effects (see ACTIVE GALAXIES: OVERVIEW; UNIFIED MODEL). For nearly a dozen Seyfert 1s, and especially for three of them (NGC 4151, NGC 5548 and NGC 7469), and for the quasar 3C 273, large international collaborations have organized long coherent campaigns of observations, some comprising simultaneous observations in the optical, UV and x-ray ranges, producing large amounts of data of uniform quality and gathered with optimum time sampling. A number of Seyfert 1s (∼30) have been monitored less extensively but still sufficiently to establish that the results from the best studied Seyfert 1s are representative.

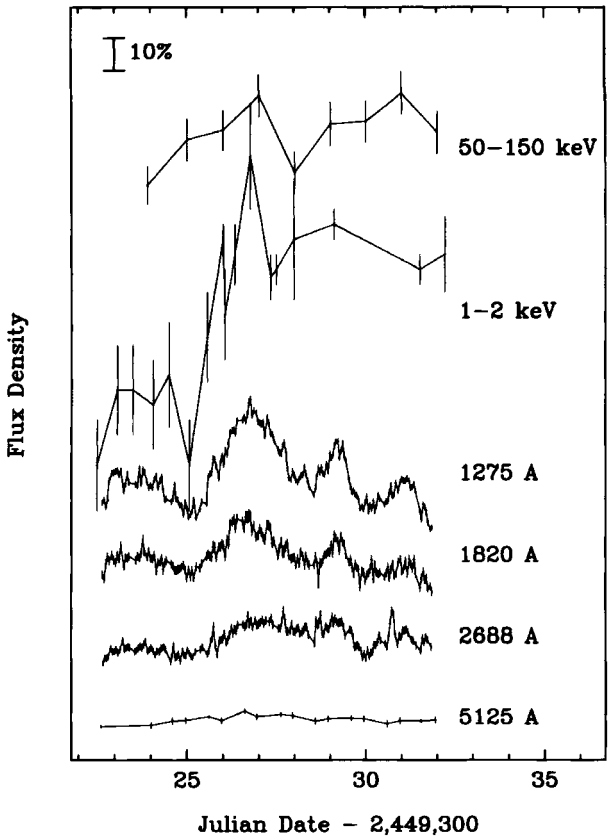

Figure 1. Variations of the continuum flux at different energies during a 10 d intensive monitoring of the AGN NGC 4151. The light curves are shifted vertically for convenience and a 10 % change is indicated by the bar. (From R A Edelson *et al* 1996 *Astrophys. J.* **470** 364)

Variability of the continuum flux

The electromagnetic spectrum (continuum spectrum) of radio-quiet AGN, after subtraction of the stellar continuum emitted by the host galaxy, extends from ∼1 mm to ∼100 keV with a prominent broad peak in the UV–extreme UV (EUV) range and a secondary peak in the IR (see ACTIVE GALAXIES: OBSERVATIONS). The x-ray emission is dominated by a power law component (1–10 keV; $\alpha \simeq 0.9$

where $f_\nu \propto \nu^{-\alpha}$), which steepens in the hard x-ray range (>50 keV), possibly with a cutoff around 100 keV.

It is recalled here that in the theory of accretion disks, the accreted matter spirals in towards the center under the gravitational attraction of the black hole. The matter, however, does not flow freely. It has an internal stress (very likely of magnetic origin) whose dissipation produces heat, and also sets the timescale of the propagation of the accreted matter towards the center. Astronomers talk about the disk being heated by viscosity and about viscous timescales, and theoreticians can calculate the energy produced by viscosity, the resulting spectrum emitted by the disk, and the timescales on which the radiation from the disk varies in response to a varying accretion rate (ACCRETION DISK). The observed spectral shape of the continuum of AGN from 1200–5000 Å (or 10–2.5 eV) is roughly consistent with thermal emission from an accretion disk. However, the variations of the UV continuum flux occur on timescales of days, weeks or months which are shorter by many orders of magnitude than the timescales expected from variations in the accretion rate. Remarkably, in NGC 4151 and NGC 5548, the medium energy x-ray flux (2–10 keV) and the optical/UV flux vary simultaneously (figure 1) with the high-energy variations being much larger than the low-energy variations.

Taken together, these observations suggest a model where the surface of the disk is irradiated by the central variable x-ray source.

The x-ray source variability itself is believed to be due to explosive reconnections of magnetic-field lines permeating the accretion disk and the corona (the gas of hot electrons surrounding the central parts of the disk) through a phenomenon reminiscent of the solar flares in the solar corona. A significant fraction of the accretion energy is spent in this way in heating the corona.

The hot electrons transfer some of their energy to ambient UV photons (emitted by the disk) and soft x-ray photons and produce medium and hard energy x-ray photons via inverse Compton emission. This 'Comptonization and reprocessing model' explains the simple correlation among x-rays and UV emission on short timescales in NGC 4151 and NGC 5548, and also explains the average slope of the x-ray spectrum, the high-energy cutoff and other features of AGN x-ray spectra.

But life is not so simple and the good correlation x-rays vs UV flux observed in NGC 4151 and NGC 5548, might have been a lucky circumstance in the intricate interplay between the hot electron gas, the UV photons, and the x-ray photons ('which is the chicken and which is the egg?'). In fact, in a third Seyfert 1 nucleus extensively observed simultaneously in the UV and x-ray, NGC 7469, the UV variations sometimes lag behind the x-ray variations and sometimes are simultaneous with the x-ray variations. This case places some serious doubt on the reprocessing picture provided earlier. A close look at the data, however, reveals a striking similarity of the variations in the two energy ranges, which suggests a basic link between the emission in the two energy ranges such as generally provided by Comptonization.

The most extreme soft x-ray variability occurs in narrow-line Seyfert 1 galaxies (NLS1), a subset of AGN with very intense soft x-ray emission and very steep soft x-ray spectra, narrow optical emission lines and prominent optical Fe II emission. To explain the absence of broad lines in NLS1, it has been proposed that the intense soft x-rays could blow away the inner broad-line region (BLR) or ionize it to states currently undetectable. The steep soft x-ray spectrum of NLS1 may indicate a high accretion rate or a small black hole mass.

Turning now to the infrared range, variations, when detected at all, are of smaller amplitude and longer timescale than in the optical, and are consistent with being the delayed response of dust around the central source to the long-term variations of the UV and x-ray continuum flux.

The emission line variations

A method to estimate the black hole mass

Monitoring of the flux variations of the continuum and the spectral line intensities of several Seyfert 1s have shown that the intensities of the spectral lines mimic the variations of the optical/UV continuum but with a certain time delay τ. This delay is interpreted as the time needed for the light from the central continuum source located in the immediate vicinity of the black hole to reach the gas clouds emitting the spectral lines (and located around the central continuum source) and increase or decrease the emissivity of the gas (figure 2).

The time delay τ gives a measure of the distance $d \sim c\tau$ of the line-emitting gas clouds from the central continuum source. This method can be expanded to map the line emission region and it is known as 'reverberation mapping'.

A rough estimate of the mass of the central black hole can then be calculated from the variations of the variable component of an emission line by combining the component width (which gives the virial velocity of the gas clouds) and τ (which is the delay by which the component variations follow the continuum variations). The assumption that the clouds' motions are orbital motions in the gravity field of the black hole is strongly supported by the fact that the blue and red wing of any line or line component vary together (i.e. one wing does not vary before or after the other one, to first order; see below).

This method of determining the mass of the central black hole has been applied to more than a dozen AGN and yields values in the ranges a few $10^6 M_\odot$ to a few $10^8 M_\odot$.

The velocity field of the gas

One of the crucial elements contributed by variability studies is that the broadest emission lines vary with the largest amplitude and on the shortest timescale, indicating that the fastest moving gas is closest to the center.

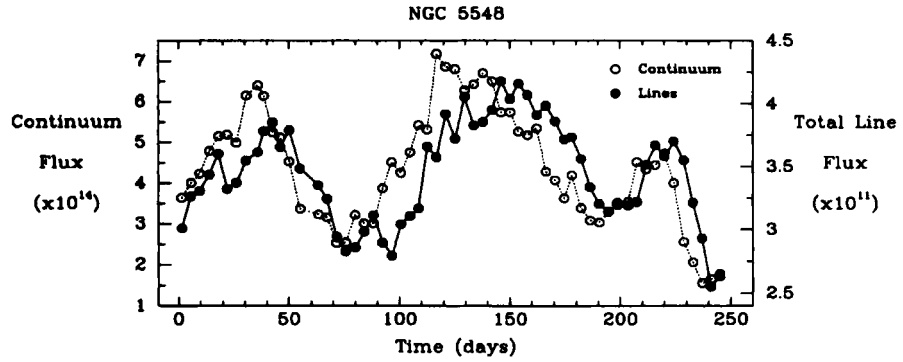

Figure 2. The UV continuum flux (open symbols; left vertical scale in erg s^{-1} cm^{-2} A^{-1}) and the emission line intensities (here the sum of all the lines; dots; right vertical scale in erg s^{-1} cm^{-2}) as a function of time for the AGN at the center of the galaxy NGC 5548. The delay of ∼15 d between the two light curves means that the lines are formed at a distance of ∼15 light d or 5×10^{16} cm. (From D Maoz 1997 *Emission Lines in Active Galaxies: New Methods and Techniques. ASP Conf. Ser.* **113** ed B M Peterson, F-Z Cheng and A S Wilson (San Francisco, CA: Astronomical Society of the Pacific) p 138.)

The detailed variations in line intensity and profile provide the answer to the question which is critical to the determination of the mass, as to whether the clouds are gravitationally bound to the central black hole: The line profile variations do not show the systematic effect of one wing responding before the other that would be expected for radial flows: The blue wing would be observed to vary first in the case of outward flows and spherical winds, and the red wing would be observed to vary first in the case of spherical accretion[1]. This, and the fact that the fastest moving gas is closest to the center, strongly suggest that the high ionization clouds are in orbital motions (chaotic or rotation motions) in the gravitational field of the black hole, with only minor components of net infall or outflow. Chaotic motions are ruled out because the gas clouds would be destroyed when crossing the accretion disk.

The most detailed result on the velocity field in the BLR comes from an intensive monitoring of the C IV line profile during 'a month in the life of NGC 4151', with nearly complete 1 d sampling over a 35 d interval. The analysis of the variations in each interval of velocity in the C IV line profile shows the variations to be consistent with gravitational motions around a mass of $\sim 10^7 M_\odot$. This value agrees with that resulting from observations of the entire UV spectrum of NGC 4151 at other epochs, which show a linear relation between the response time of a line and the inverse square of the line width. A similar study of NGC5548 yields a mass of $(5 \pm 3) \times 10^7 M_\odot$. Note that in both NGC 5548 and NGC 4151, there is possibly a weak signature of an infall component. Other AGN give consistent results (albeit less detailed) and it is tentatively concluded that the line width is dominated by rotation. This forms the basis of the estimate of the black hole mass from the response of the emission line intensities to the continuum flux variations. The uncertainties attached to this method are difficult to evaluate and are probably less than a factor 10.

[1] Take the example of an expanding sphere of gas whose emissivity varies under the influence of the varying central continuum. A signal from the central source—for example, an increase of flux—reaches all the points of the sphere simultaneously, but the first signal which we receive from the sphere originates from the part closest to us and which is in motion towards us. We will, therefore, first observe an increase of the short-wavelength part, or blue wing, of the emission line.

The 'disk and wind' model

In AGN spectra there are low-ionization lines, such as the Balmer lines and lines of Fe II and Mg II, and high-ionization lines (the strongest are lines of C IV, N V, He II, Si IV). Interpretation of the observations show that the low-ionization lines come from a flat aggregate of very dense clouds ($N_e \geq 10^{11}$ cm^{-3} and total optical thickness of 10^{24} cm^{-2}) which is identified with the relatively cool part (surface temperature of 5000 K) of the accretion disk.

The high-ionization lines, in contrast, come from a comparatively more dilute medium, above and below the disk, the lines of the most highly ionized elements being the broadest. This indicates that the degree of ionization is correlated with the gas velocity (figure 3).

Remarkably, the high-ionization lines are not exactly at the redshift of the low-ionization lines (emitted by the accretion disk), which themselves are at the host galaxy redshift. They are blueshifted (by 0 to ∼1500 km s^{-1}) with respect to the disk and the host galaxy, indicating that the highly ionized gas is flowing out towards us. (By symmetry, a flow is probably moving away from us, on the other side of the disk, but is hidden from view because the disk is opaque). The combination of rotation and outflow from the disk suggests and is consistent with a model where the high ionization lines are emitted by gas clouds emerging from the disk, still retaining a large part of the angular momentum that the gas had in the disk.

Such motions are predicted by the magnetohydrodynamical model of accretion disks in which magnetically accelerated winds are formed from filaments pulled from the originally dense low-ionized material of the accretion disk and subjected to the intense central ionizing field. This

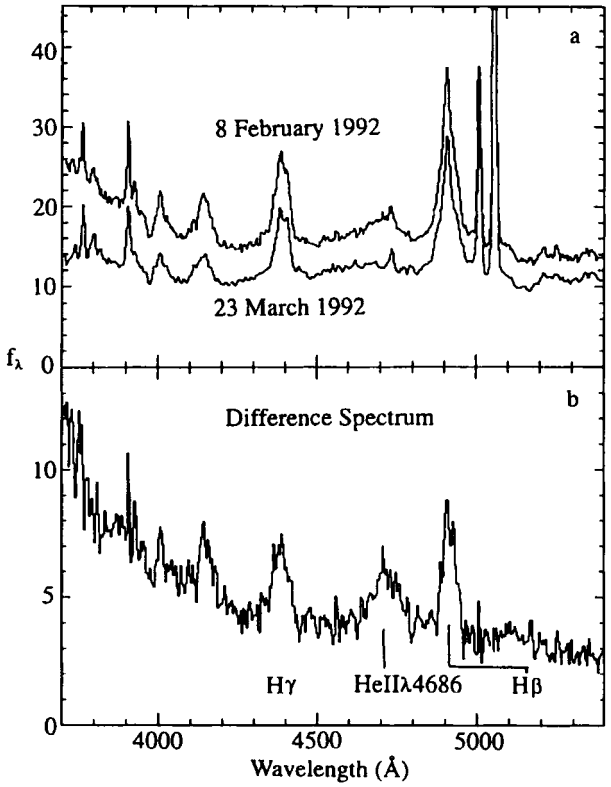

Figure 3. The variations over 44 d of the optical spectrum of the active nucleus of NGC 3783. The difference between the two spectra illustrates the large width and variability of the high ionization line of He II as compared to the other lines. The continuum spectrum is steeper at high state, a general property of AGN. Same unit of flux on both panels, 10^{-15} erg s^{-1} cm^{-2} A^{-1}. (From G M Stirpe *et al* 1994 *Astrophys.J.* **425** 609)

forms a highly ionized wind above and below the disk. The physics of these phenomena, however, is complicated and many features of this promising model remain unspecified at present.

Current problems and future developments

There remain a number of questions and exciting avenues of investigation.

First, the theoretical investigation of the magneto-hydrodynamical effects which, together with the gravity field of the black hole, dominate the physics in the black hole surroundings needs to be vigorously pursued.

Second, the variability phenomenon has been best observed and is best understood in the case of the medium luminosity AGN (total luminosity $L \sim 10^{42}$–10^{45} erg s^{-1}), but variability data on powerful quasars (up to 10^{49} erg s^{-1}) and on very low luminosity AGN (10^{39} erg s^{-1}) are still very few. Fortunately, the relevant observations are under way. They will make it possible to investigate the entire parameter space defined by the black hole mass and the accretion rate and to understand the specific characteristics of the accretion process in the different regions of this parameter space (e.g. advection, accretion of single stars, super-Eddington accretion rate).

Finally, although this article is focused on the directly observable variability of AGN, i.e. occuring on timescales of hours to years, it is pointed out that other variability phenomena must occur on longer timescales, say 10^2, 10^6 or 10^9 yr. Particularly relevant to this is the recent discovery (from measurements of the velocities of stars in the nucleus of nearby galaxies) that black holes are likely to be present in the centers of non-active galaxies, including our own Galaxy, with masses roughly in the same range of values as those determined from AGN investigations. A number of questions then naturally arise such as to whether AGN could be recurrent phenomena with dormant phases, and whether they can be fuelled by gas produced through the evolution of the stars in the host galaxy or whether the accreted material always come from outside the host galaxy.

Active Galactic Nucleus

The central region of an active galaxy within which exceptionally large amounts of energy are being generated. An active galactic nucleus (AGN) emits strongly over a wide range of wavelengths, from x-ray to radio, the most powerful examples radiating a thousand times as much energy as the galaxies within which they are embedded. Typical luminosities range from about 10^{37} to 10^{39} or even 10^{40} watts. The spectrum of the radiation emitted by an AGN is markedly different from that of an ordinary galaxy (which shines with the combined light of its constituent stars and nebulae) and implies that some mechanism other than stellar radiation is needed to explain its copious output of energy. Many AGNs appear to be ejecting jets of highly energetic particles. In some cases one jet is seen, in others two oppositely directed jets are visible.

Many AGNs vary in brightness by substantial amounts over timescales as short as years, months, days, or even hours. Because a source of light cannot vary in brightness on a timescale shorter than the time taken for light to cross the diameter of the source, these short-term variations imply that the energy sources in AGNs must be very compact. For example, if an AGN varies in one year, its energy source must be no more than a light-year across; if it varies in one day, its energy source must be less than a light-day across. Consequently, some AGNs appear to be radiating up to a thousand times as much energy as a conventional galaxy from a region of space comparable in size to the solar system.

A widely supported hypothesis suggests that each and every AGN contains a supermassive black hole, with a mass of between ten million and several billion solar masses that is accreting matter from its surroundings. Because all galaxies are rotating, infalling matter will preserve its angular momentum (rotational motion) and will form a rapidly spinning disk of gas (an accretion disk) around the central black hole. Kinetic energy provided by infalling matter as it ploughs into the disk, and frictional effects within the disk, raise the temperature of the disk to very high values, causing it to radiate copious amounts of energetic radiation. The gravitational energy released by infalling matter is more than adequate to account for the power outputs of all types of active galactic nuclei. Because a black hole is so small compared with the size of a galaxy, and most of the energy is radiated from the inner regions of the accretion disk, this model neatly accounts for the very compact nature of the energy sources in AGNs.

By a process that is still not fully understood, the central 'engine' accelerates streams of charged particles to relativistic speeds (large fractions of the speed of light). The inner part of the disk is believed to form a nozzle that confines the outward flow of energetic particles into two oppositely directed jets that shoot out perpendicular to the plane of the disk.

Many astronomers believe that the same basic model (the 'unified model') can account for all kinds of active galaxy (Seyfert galaxies, radio galaxies, quasars, BL Lacs and blazars). According to this model, the supermassive black hole and its inner accretion disk is surrounded by a thick dusty torus ('donut') of matter, and the type of active galaxy that is seen depends on the orientation of the torus and jets relative to the observer's line of sight. The jet radiates most strongly along its axis. The view of an observer, who is looking along, or very close to, this axis, will be dominated by the head-on jet, and a violently variable source with no spectral lines (a BL Lac or blazar) will be seen. Looking at a modest angle to the jet, an observer will see an unobscured compact source (a quasar) inside the torus. From a viewpoint closer to the plane of the torus, the central 'engine' is hidden from view, and we see only the jets and lobes (extended radio-emitting clouds) of a radio galaxy. A similar picture applies to Seyfert galaxies, a type II Seyfert being seen when the central engine and the gas clouds in its vicinity are hidden, and a type I Seyfert when the observer's line of sight looks over the rim of the torus towards the innermost regions of the AGN.

There is strong observational evidence to support the suggestion that active galactic nuclei contain supermassive black holes. In particular, scans across the centers of a significant number of active galaxies have shown that the intensity of starlight rises sharply in a central brightness 'spike' in a way that is consistent with stars being bunched together in the gravitational field of a highly massive compact object. Furthermore, where it has been possible to measure the orbital velocities of gas clouds in the innermost cores of active galaxies, the results indicate that these clouds are moving in the gravitational fields of extremely massive compact objects. For example, measurements of the intensity of light and the rotational velocities in the core of the giant elliptical galaxy M87 (in the Virgo cluster) are consistent with the presence of a supermassive black hole of some three billion solar masses. Furthermore, high-resolution images obtained by the Hubble Space Telescope have revealed flattened disks of gas and dust in the cores of a number of active galaxies.

Active Galaxies: Observations

'Active galaxy' is a general term which refers to any galaxy that produces significant emission in addition to that from its constituent stars, stellar remnants and interstellar medium. The characterization of such galaxies as 'active' is because the unusual emission characteristics are generally assumed to be associated with high-energy, eruptive phenomena. The earliest consistent user of the word 'activity' as applied to the nuclei of galaxies seems to have been V A Ambartsumian.

In most cases, this non-stellar emission appears to originate in the very center, or nucleus, of the galaxy, and these sources are known generically as 'active galactic nuclei' (AGN). A galaxy that harbors such a source is known as the AGN host. Historically, some other types of sources, such as STARBURST GALAXIES, that have some phenomenological similarities to AGN (e.g. strong near-UV emission) have also been known as active galaxies, though in these cases the activity might not be confined to the nuclear regions.

AGN are the most luminous long-lived sources in the universe. They emit strong radiation over the entire observable wavelength range, from x-rays and γ-rays through long-wavelength radio. A complete picture of the emission of an AGN can be obtained only by observing it at many wavelengths, preferably simultaneously over the entire spectrum because they are variable sources. There are a number of different classes of AGN (see ACTIVE GALAXIES: OVERVIEW); SEYFERT GALAXIES constitute the low-luminosity end of the AGN phenomenon, i.e. their nuclear luminosities are roughly comparable with the total starlight from the host galaxy. Higher-luminosity AGN are known as 'quasars' or 'quasi-stellar objects' (QSOs) (see QUASISTELLAR OBJECTS: OVERVIEW) with the former being reserved (originally) for the stronger radio sources, and the latter weaker; in these cases the optical light from the AGN can exceed, sometimes by factors of more than 100, the stellar light from the host galaxy at all wavelengths. There are a wide variety of subclasses within these groups, based on the relative prominence of UV–optical emission lines, radio properties and polarization (see POLARIZATION IN ACTIVE GALAXIES). These will be mentioned below as necessary.

This section will discuss the current status of observations over the electromagnetic spectrum. We first discuss the continuous emission of AGN in terms of their 'spectral energy distributions' (SEDs), i.e. amount of energy emitted in various wavebands. We then focus on the prominent emission lines that are detected in the UV–optical (and, more recently, x-ray) spectra of most AGN and follow this with a brief description of absorption features in AGN spectra. Spatially resolved structures in AGN are also discussed.

Spectral energy distributions

The SEDs of normal stars (and galaxies) are well approximated as blackbodies in the temperature range 2000–50 000 K, and thus their emission is strongly concentrated in the ultraviolet (UV) through near-infrared (IR) parts of the spectrum. In contrast, AGN emit comparable energy (per unit logarithmic bandwidth) over most of the observable spectrum, as can be seen in figure 1. The one exception is the radio region, in which 'radio-loud' (RL) AGN are some 3 orders of magnitude brighter than their 'radio-quiet' (RQ) counterparts. These RL AGN constitute ~10% of the population. Figure 1 shows the low-redshift median SED for RL and RQ objects from a sample of more than 40 AGN. It is plotted as $\log(\nu L_\nu)$ versus $\log \nu$, which shows the energy output in each waveband and also highlights the important structure in the SED.

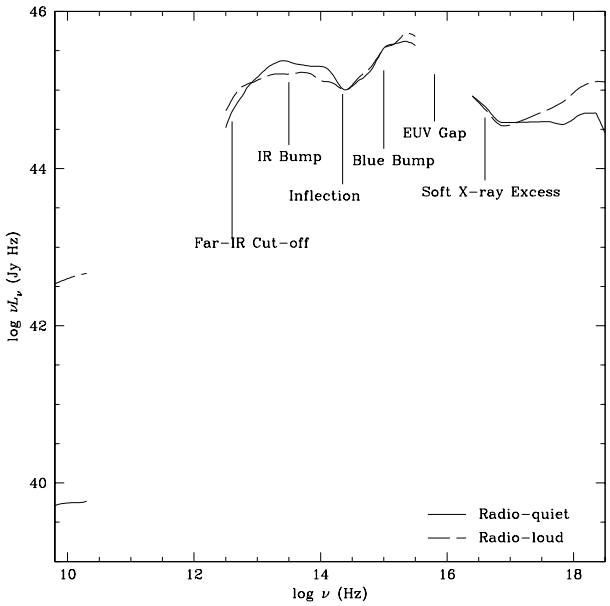

Figure 1. The median radio–soft x-ray spectral energy distribution for radio-loud (dashed) and radio-quiet (solid) low-redshift quasars. Data from Elvis *et al* 1994 *Astrophys. J. Suppl.* **95** 1.

Our knowledge of these SEDs is limited by current observational technology to fairly low-redshift, bright sources and includes (as is clear in figure 1) important gaps in various wavebands.

1. The absence of observations at high energies (γ-rays) is due to current technical limitations; higher-energy detectors are not sensitive enough to detect most AGN. Those that have been detected so far are generally core-dominated (CD) RL AGN, i.e. those whose emission is boosted by a relativistic flow along our line of sight (see ACTIVE GALAXIES: UNIFIED MODEL for more detail).
2. The EUV gap, between the far-UV and soft x-ray regions of the spectrum (i.e. between 912 Å and about 0.1 keV, spanning a factor of about 10 in photon energy), is due to the large opacity of the interstellar

medium in our own Galaxy to hydrogen-ionizing photons. Photons in this energy range are especially important because these drive the strong emission lines seen throughout the UV and optical spectra of AGN.

3. The gap between the submillimeter and short-wavelength radio is again due to technological limits. New detectors and satellites have recently reduced these limitations considerably and revealed sharp far-IR spectral breaks for all but the CD RL AGNs.

The most prominent feature of AGN SEDs is the strong peak in the UV spectrum. The feature, which is often known as the 'big blue bump' (BBB), begins in the near-IR and may extend all the way to soft x-ray energies. It is observed with a combination of low-resolution optical and UV spectroscopy and/or multicolor, optical photometry. It can be plausibly identified as arising in an accretion disk (AD) containing material with a wide range of temperatures and orbiting around a supermassive black hole. The BBB peaks in the extreme UV, which is consistent with the expected emission from an AD around a $\sim 10^8 M_\odot$ black hole that is accreting material at the Eddington rate.

The IR emission from RQ AGN is mainly observed via multicolor photometry, although IR spectroscopy is a rapidly expanding field. The IR spectrum is thought to be dominated by thermal emission from dust in the host galaxy or a molecular torus that surrounds the AGN. The most compelling evidence for this interpretation is as follows.

1. There is a local minimum in AGN SEDs at a wavelength of about 1 μm. This probably represents emission from the highest-temperature (about 1500 K) grains that can exist in the vicinity of an AGN; at higher temperatures, i.e. smaller distances from the central source, dust will sublimate.
2. In some AGN, the infrared continuum has been observed to vary, apparently in response to earlier, similar continuum variations in the UV–optical spectrum (see ACTIVE GALACTIC NUCLEI: VARIABILITY). The light-travel time inferred is consistent with the maximum distance at which grains exposed to the AGN radiation field should sublimate.
3. The sharp break in the far-IR–submillimeter region of the SED in all but CD RL AGNs is generally too steep to be ascribable to optically thick synchrotron emission or to single-temperature blackbody emission, but is consistent with thermal emission from grains (depending somewhat on the unknown grain emissivity law).

In RL AGN, the IR is probably a mix of isotropic thermal and beamed non-thermal emission. The beamed emission dominates in the CD RL AGN as it is boosted by relativistic outflow along our line of sight. Strong evidence for this interpretation is provided by the coordinated variability observed in several of these sources, most notably 3C 273, which is the brightest nearby QSO and consequently has been extensively monitored. Preliminary results in the mid- and far-IR from the ESA satellite *ISO* show the progression from non-thermal to thermal emission in a small sample of CD and lobe-dominated RL AGN and RQ AGN, supporting this general picture.

While the UV–optical–IR emission from AGN appears to be predominantly thermal in origin, both the high- and low-energy extremes of the observable SEDs are thought to be produced by non-thermal processes. X-ray observations of AGN are largely confined to very low-resolution spectroscopy which yields the global continuum shape. The principal feature of RQ AGN hard x-ray spectra is a power-law continuum ($F_\nu \propto \nu^{-\alpha}$, with $\alpha \approx 0.9$) over the range $\sim$1–100 keV. The spectrum generally turns over at energies $\gtrsim$100 keV and is thought to arise through repeated Compton scattering of thermal or non-thermal photons.

RL AGN show a harder x-ray spectrum than their RQ counterparts (Figure 1). The relative strength of this hard component increases with the core dominance of the radio source, implying that the emission is beamed similarly to the radio and supporting an origin in Compton up-scattering of the radio synchrotron photons. CD RL AGN are, to date, the only AGN detected in the high-energy γ-rays, implying that beaming is a key factor. A few very high-energy observations have been made, including ground-based detection of Cerenkov showers that occur when TeV energy photons hit the Earth's atmosphere. So far, the AGN detected by this method are all BL Lac objects (see BL LACERTAE OBJECTS). Similar to CD RL AGN, the observed emission from these sources is apparently dominated by a relativistic beam or jet (see ASTROPHYSICAL JETS) directed towards the observer.

At energies around 10 keV and above, RQ AGN spectra also have a 'hard tail' above the x-ray power law which is stronger in lower-luminosity sources. This is thought to arise through 'Compton reflection' (a combination of inelastic scattering of higher-energy photons and photoelectric absorption of lower-energy photons) off relatively cooler material. This feature is strong enough that the cooler material must cover about half of the sky as seen from the x-ray source itself, which has led to speculation that the reflecting body must be the AD itself, with the x-ray source located somewhere above it. An example of such a spectrum is shown in figure 2.

Spectral variability

One of the most remarkable characteristics of AGN is their strong flux variability. Indeed, the very existence of intraday continuum variability puts a severe upper limit (set by light travel time and source coherence arguments) on the size of the continuum source, and thus provides one of the strongest arguments for identifying an AD around a supermassive black hole as the source of continuum radiation. At a fundamental level, the cause of continuum

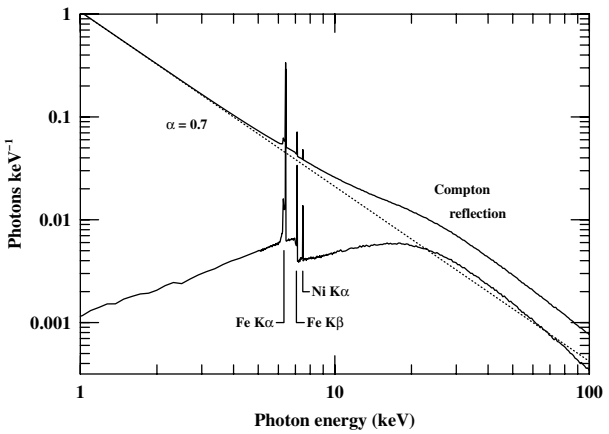

Figure 2. An x-ray reflection model with an input power spectrum $F_\nu \propto \nu^{-0.7}$ (dotted line) irradiates a slab of 'cold' ($T < 10^6$ K) gas in the limit of zero height on the disk axis. The lower spectrum shows the reflected spectrum, in which fluorescence lines appear prominently. At high energies, the reflected spectrum turns down as a result of Compton down-scattering within the slab. Data courtesy of I George, figure from Peterson (1997).

variability is not understood, although AD instabilities are sometimes invoked as a driving mechanism.

In general, the most rapid and highest-amplitude variations are seen at the highest photon energies. X-ray flux variations have been detected in Seyfert galaxies on time scales as short as several minutes. For phenomenological purposes, we can characterize the strength of the variations as a function of temporal frequency f by their 'power density spectra', which are conventionally modeled as a power law, i.e. $P(f) \propto f^{-\alpha}$ where α is typically in the range 1–2 for most AGN. The case $\alpha = 0$ is 'white noise', i.e. the amplitude of variation is independent of time scale, and $\alpha = 1$ corresponds to variations that can be described as a random walk. Larger values of α correspond to increased amplitudes of variability over longer time scales (lower frequencies f). In some cases, e.g. NGC 4151 and 3C 390.3, the most prominent variations seem to occur quasi-simultaneously (i.e. simultaneous to within less than a day) from x-rays (or even γ-rays for NGC 4151) through to optical wavebands. The smaller-amplitude structures in the light curves differ across the spectrum, with lower amplitudes and less structure seen at lower photon energies. The near-simultaneity of the variations requires that the variations are driven by radiation rather than, for example, by propagation of disturbances through the AD on the much-longer viscous time scale. These observations, along with detection of the x-ray hard tail and the Fe Kα emission line, point to 'reprocessing' models, in which a variable x-ray source illuminates the AD from above, with the absorbed x-ray energy driving variations observed at lower photon energies.

In at least one case (the Seyfert galaxy NGC 7469), however, the x-ray variations do not correlate well with the UV–optical variations; variations of similar fractional amplitude are seen in both the x-ray and UV–optical regions, but there is no clear causal relationship between them.

It is in this same object, however, that a time delay between UV and optical variations has been detected. This is the only Seyfert galaxy that has been monitored sufficiently well for such wavelength-dependent continuum time delays to be detected. Relative to the variations in the shortest-wavelength UV, variations at longer wavelengths are delayed by an amount $\tau \propto \lambda^{4/3}$, which is precisely the wavelength dependence expected if the variations arise in a thin AD that is irradiated by a variable x-ray source. Of course, this interpretation fails utterly to account for the observed lack of correlation between the UV–optical and x-ray variations. At this time, NGC 7469 seems to present serious difficulties for reprocessing models, although no other explanation of the coupling (or lack of coupling) between the x-ray and UV–optical variations has been forthcoming.

Extreme flux variations are observed in BL Lac objects as well. In this case, however, the fundamental origin of the variations is probably related to the propagation of shocks through the relativistic jet. Unlike the Seyferts, while there is a close correspondence between the variations in different bands, a completely consistent relationship between time delay and wavelength has not yet emerged; the same source can apparently show different behavior at different times, and the reason for this is not understood.

Emission lines

Basic properties of UV–optical lines

Strong broad emission lines are a defining characteristics of all types of AGN, except BL Lacertae objects in which the, presumably present, emission lines are swamped by the highly beamed continuum emission from the jet. In the UV–optical–IR part of the spectrum, the most prominent emission lines (those with equivalent widths[1] larger than some tens of Å) are usually Ly$\alpha\lambda$ 1215, C IV λ 1549, C III] λ 1909, Mg II λ 2798, Hβ λ 4861, Hα λ 6563 and Pα λ 1.88μm (figure 3). In most Seyferts and quasars, the observed emission arises in two physically distinct regions, a spatially compact (10^{15}–10^{17} cm) 'broad-line region' (BLR) with relatively high particle densities ($n_e \approx 10^{11}$ cm^{-3}) and large velocity dispersions ($v_{FWHM} \approx$ 1000–10 000 km s^{-1}), and a spatially extended (100 pc–1 kpc) 'narrow-line region' (NLR) with relatively low particle densities ($n_e \approx 10^3$ cm^{-3}) and smaller velocity dispersions ($v_{FWHM} < 1000$ km s^{-1}). Certain nebular 'forbidden' lines, such as [O III] $\lambda\lambda$ 4959, 5007, are prominent features of narrow-line spectra but are not observed in broad-line spectra. In the low-density NIR, both the Balmer lines and the [O III] are in the low-density limit in which the emissivity is proportional to n_e^2. However, in the denser,

[1] The equivalent width of an emission line can be thought of as the width (in wavelength units) of underlying continuum that would be required to produce the same emission-line flux.

but much lower-mass BLR, the Balmer lines are still in the low-density limit, but the [O III] lines are in the high-density limit in which the emissivity is proportional only to n_e. The [O III] lines from the broad-line region are thus very weak relative to the Balmer lines, and the forbidden lines are often referred to as being 'collisionally suppressed'.

Seyfert galaxies have traditionally been divided into two spectroscopic subclasses: type 1 Seyferts have both broad-line and narrow-line emission, whereas type 2 Seyferts have only narrow lines. In some and possibly all cases, the type 2 objects are those whose BLRs are obscured from our direct vision by dust. Spectra of quasars are always similar to those of type 1 Seyferts. The question of whether or not there are any *bona fide* 'type 2 quasars' remains open. Recent polarimetry has revealed broad lines in some ultraluminous infrared galaxies: spectroscopically these could sometimes be classified as the elusive type 2 quasars, but fundamentally these are still obscured type 1 quasars. Beyond semantics, the question is whether or not unified models explain all type 2 objects.

Emission-line variability

The broad components of AGN emission lines vary in flux in response to changes in the continuum flux, with time delays that are assumed to be due to light travel-time effects within the BLR. Indeed, measurement of the BLR size relies on measurement of the mean time delays (or 'lags') between continuum and emission-line variations. This process, known as 'reverberation mapping', has been carried out successfully for more than two dozen AGN. The BLR sizes in Seyfert galaxies are in the range of a few to around 100 light-days (i.e. $r_{\rm BLR} \approx 10^{15-17}$ cm), and scale with luminosity approximately as $r_{\rm BLR} \propto L^{1/2}$, consistent with the simplest theory. Different lines in a given AGN respond with different time delays, usually in the sense that higher-ionization lines respond faster than lower-ionization lines; this indicates that the BLR has a radially stratified ionization structure and that the maximum variability response of different lines occurs at different radii. The range of time responses is such that the outer edge of the BLR is at least 10 times larger than the inner edge.

In principle, reverberation mapping should be able to determine the velocity field of the BLR because the broad lines are resolved in line-of-sight (Doppler) velocity. For example, if the BLR clouds were traveling radially outwards from the central source, then an external observer would see the short-wavelength (relatively blueshifted) gas on the near side of the nucleus respond to continuum variations before seeing the long-wavelength (relatively redshifted) gas on the far side of the nucleus. The absence of such a strong signature indicates that the predominant gas motions are not radial. However, current observations are not extensive enough to determine whether the BLR gas is confined to a disk or has some different geometry.

Regardless of the details, if it is accepted that the BLR gas motions are primarily orbital around the central source, the mass of the central source ($M_{\rm black\,hole}$) can be measured by combining measurements of the size of the region with emission-line width, i.e. to within some geometry-dependent factor of order unity, $M_{\rm black\,hole} \approx r_{\rm BLR}\, v^2_{\rm FWHM}$. For the two dozen or so low-luminosity AGN for which this has been done, masses in the range (10^6–10^8)$M_\odot$ have been inferred.

The narrow emission lines generally do not vary on time scales of years or less because the longer light-travel and recombination times tend to smear out the effects of any continuum variations. Reports of narrow-line variability are rare. Probably the best case for actual narrow-line variability is the case of the broad-line radio galaxy 3C 390.3, which seems to have an abnormally compact, high-density NLR.

Narrow-line widths seem to correlate well with the central masses of the AGN host galaxy on scales comparable with the size of the NLR (i.e. the interior galactic bulge mass), although there is also clear evidence that part of the narrow-line widths and asymmetries is due to interaction with jets.

The x-ray iron (Fe) Kα line

In the low-resolution spectra typically obtained in the x-ray region by satellites such as ASCA (Japan), SAX (Italy) and RXTE (USA), a fluorescent Fe Kα emission line is commonly observed. This emission line tends to be stronger in lower-luminosity sources. The energy at which the line is observed crudely indicates the ionization state of the emitting material. A wide range of behavior is seen from unresolved, cool lines (i.e. from low-ionization material), consistent with an origin in absorbing material along our line of sight through the quasar, e.g. the molecular torus, to hot, resolved lines with widths, $v_{\rm FWHM} \gtrsim 10\,000$ km s^{-1}, which imply material much closer to the central AGN than the UV and optical lines discussed above. In a few of these, most notably MCG-6-30-15,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

complex line profiles are observed which suggest emission from very close to the central AGN. This interpretation is very attractive as the line then provides our only direct observation of the inner AD and is extremely important for diagnosing and constraining both AD and central-source models.

X-ray satellites, such as XMM (ESA) and the Chandra X-Ray Observatory (NASA), both launched in 1999, will be able to observe Fe Kα emission in a larger fraction of the AGN population. Their gratings will also provide extremely high spectral resolution ($E/\Delta E > 100$–1000), allowing more detailed profile studies as well as the detection of more and weaker lines in bright, nearby AGN.

Spatially resolved structures in AGN

The narrow-line region

Whereas the size and structure of the BLR must be inferred indirectly by processes such as reverberation mapping, the NLR is sufficiently extended that, in the nearer AGN, it can be spatially resolved with the Hubble Space Telescope or, in some cases, even with ground-based observations. The NLR is typically approximately axisymmetric, with its long axis coinciding with the radio axis in those sources in which extended radio emission is detected. In some cases, there appear to be shock fronts at the interface between the radio-emitting plasma and the interstellar medium in the host galaxy. While the narrow-line emission is apparently driven primarily by photoionization by the central source, strong emission from post-shock cooling regions is also detected.

In some cases, narrow-line emission seems confined to wedge-shaped 'ionization cones' that emanate from the nucleus. The opening angles of these cones are typically 30°–100°. These cones are thought to be a result of anisotropy in the AGN radiation field that is introduced on much smaller scales by an obscuring torus that surrounds the central source.

AGN host galaxies

In the present-day universe, AGN constitute fewer than 5–10% of all bright galaxies. Why are some galaxies 'active', whereas others are not? Does the AGN phenomenon represent a transient phase in galaxy evolution (noting that there were far more AGN in the distant past than there are today? Attempts to address these problems have led to studies of the 'host galaxies' of AGN. This is often a difficult undertaking, since AGN are typically at large distances, so the host galaxies are faint and have small angular sizes, and, in the case of quasars in particular, much of the host-galaxy light is simply lost in the glare of the quasar.

Carl Seyfert's original list of high-surface-brightness emission-line galaxies was composed almost entirely of spiral galaxies. Over time, the definition of 'AGN' has become primarily spectroscopic (based on the presence of strong emission lines, except in the case of BL Lac objects). High-luminosity AGN are found in both elliptical and spiral galaxies, although at low redshift RL AGN are found preferentially in ellipticals.

Until relatively recently, it was generally believed that there is a correlation between AGN and host-galaxy luminosity: more luminous AGN reside in more luminous galaxies. There are, however, strong selection effects that can lead to such a conclusion. Recent observations of quasars with the Hubble Space Telescope (to aid detection of faint host galaxies with high-luminosity AGN) and more through survey work on nearby galaxies (to find weak AGN in luminous hosts) have not supported the existence of a strong correlation between AGN and host-galaxy luminosities. Faint AGN are found in both low- and high-luminosity host galaxies, whereas high-luminosity AGN are found only in more luminous hosts.

As a result in a large part of observations with the Hubble Space Telescope, it now seems that virtually *all* galaxies harbor supermassive black holes in their nuclei (see SUPERMASSIVE BLACK HOLES IN AGN). Identification of supermassive objects requires measurement of high velocity dispersions on small spatial scales (thus requiring the high angular resolution obtainable with space-based imaging), leading to virial mass measurements. The most interesting question now seems to be shifting from 'do supermassive black holes exist?' to 'why are some supermassive black holes accreting mass (AGN) whereas others are not (normal galaxies)?' Whether or not the nucleus is fueled may be related to how easy it is to drive gas into the galaxy nucleus, and this may in turn depend on host-galaxy characteristics.

Extended x-ray emission

The high (for the x-ray) spatial resolution of the High Resolution Imager on the ROSAT x-ray satellite (~5″) facilitated imaging of bright, nearby Seyfert galaxies such as NGC 1068 and NGC 4151. X-ray imaging shows that a significant fraction (up to ~50%) of the x-ray emission can originate in an extended region around the central AGN. In a few sources, this x-ray emission is spatially correlated with the NLR. The origin of the extended x-ray emission could be due to electron scattering of the central x-ray emission or to x-ray emission from a hot, outflowing wind. The Chandra X-Ray Observatory (NASA) with its unprecedented spatial resolution (~0.5″) will allow many more of these spatial studies to be made.

Megamaser emission

Among the most exciting observations of AGN in recent years are those of water maser emission in the radio regime. Radio observations, because of the long wavelengths and correspondingly larger telescopes that can be built or synthesized[2], are currently unsurpassed

[2] The required surface accuracy of a telescope is proportional to the wavelength at which it is to be used. The relatively crude surface accuracy required for a radio telescope means that large collecting surfaces are comparatively easy and cheap to fabricate and maintain. Furthermore, the low frequencies involved make it relatively easy to correlate signals from individual radio receivers separated by large distances and thus attain higher angular resolution through interferometry.

in the spatial resolution they can obtain, typically down to milliarcsecond (mas) levels. Recent observations of water maser emission in the low-luminosity Seyfert 1.9 galaxy NGC 4258 has shown several components whose velocities accurately follow a Keplerian rotation curve. Combined with their angular positions, these maser sources indicate a warped, inclined, geometrically thin, sub-parsec-scale, molecular disk, and lead to an estimate of $(3.5 \pm 0.1)\times10^7 M_\odot$ for the mass of the central black hole, the first direct and precise such measurement. Maser observations of other sources have also provided information on similar scales, but so far none as detailed as NGC 4258.

Absorption lines

Optical and UV

The optical and UV spectra of AGN contain absorption features due to material along the line of sight between us and the optical–UV continuum source both within the AGN itself and in intervening space.

The intervening absorbers, whose redshifts are always lower than those of the background QSO, are most numerous in high-redshift QSOs with their correspondingly longer line of sight. They are dominated by lines from the fundamental transition of neutral hydrogen, Lyα λ 1215. Known as the 'Lyman α forest', these lines provide a wealth of information concerning the distribution of cold material in the universe. The range of column densities in these absorbing systems is wide, $N_{\rm H} \approx 10^{13}$–$10^{21}$ cm^{-2}, so that metal features, Mg II λ 2798, C IV λ 1549 and Lyman limit breaks are observed in a subset. At high redshift, where only the brightest sources, mostly QSOs, are visible to us, the Lyman α forest provides our only view of the cold material and so is a very important window on the early universe for cosmological studies (see QUASISTELLAR OBJECTS: INTERVENING ABSORPTION LINES).

The most interesting class of absorbers, in terms of QSO studies, is that of associated–intrinsic absorbers. These are high column density, metal line systems which occur in more than 50% of all AGN and whose redshift is close to and sometimes even slightly in excess of that of the background QSO. In UV–optical spectra with sufficiently high resolution ($\lesssim$5 Å), the lines are often visible within the broad emission-line profiles. This makes them difficult to study as neither their profiles, which often include multiple components, nor those of the emission lines they absorb are known. High-resolution and signal-to-noise data are required and, even then, the uncertainties tend to be high. The absorption is thought to originate in material close to the nucleus of the QSO and moving relative to it, usually in an outward direction. They show a range of ionization from low, where Mg II is the dominant line, to high, where C IV or even O VI λ 1034 predominate. These high-ionization absorbers are thought to also be responsible for the x-ray warm absorbers discussed below.

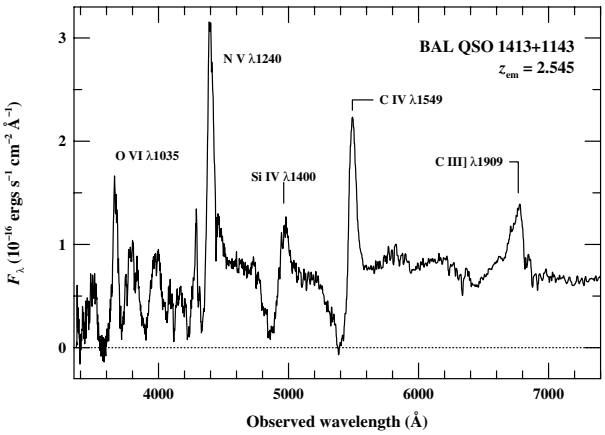

Figure 4. An example of a QSO spectrum showing BALs. Data courtesy of C B Foltz, figure from Peterson (1997).

X-ray warm absorbers

The soft x-ray spectral region is strongly affected by atomic absorption due to any material along the line of sight between us and the x-ray source within the AGN itself. Our Galaxy has a significant column density of neutral (cold) material whose signature is present in AGN soft x-ray spectra (in the range 0.1–5 keV). The host galaxy of the AGN produces a similar signature. In addition to this cold absorption, absorption by ionized (warm) material is often observed in the soft x-ray spectra. This is generally evidenced by the presence of strong absorption at the edge(s) of highly-ionized oxygen (O VII or O VIII) or, in lower-resolution data, a 'leakage' of soft photons above the expectations of cold absorption since the low-energy opacity decreases as the ionization increases.

Indications are that all or nearly all QSOs showing x-ray warm absorption also have associated absorption lines in the UV which include high-ionization lines such as O VI and N V λ 1240. Recent work has shown that high-column-density, outflowing material can produce both the x-ray and the UV features of such absorbers. The resulting combination of UV and x-ray constraints on the absorbing material has provided us with unprecedentedly strong diagnostics for the absorber. It appears to be high-column-density ($N_{\rm H} \approx 10^{20-22}$ cm^{-2}) material, outflowing from the central regions at velocities $\sim$100–1000 km s^{-1}, located between the BLR and NLR at $\approx10^{17}$ cm and often including several distinct components within an individual system.

Broad absorption lines

The most dramatic absorption features seen in the UV–optical spectra of QSOs are the broad absorption lines (BALs) (figure 4). These are high-column-density ($N_{\rm H} \approx 10^{20-23}$ cm^{-2}) intrinsic absorbers outflowing from the QSO nucleus. They have a range of ionization (hence C IV or Mg II BALs) and a wide range of velocities sometimes approaching $\sim$10% of the speed of light. The absorption generally contains a great deal of structure although a

small subset have smooth P-Cygni-type profiles indicating a smooth, spherical outflow. Since they absorb out so much of the QSO continuum and line emission, it is very hard to study them quantitatively. High-resolution and high-signal-to-noise spectra are essential along with detailed modeling of both emission and absorption features in order to build up information on the column densities as a function of velocity for this material. Interpretation is generally in terms of a turbulent, outflowing wind close to the QSO nucleus and covering a significant fraction of the central continuum source and the BLR. These sources are universally weak x-ray emitters, mostly undetected down to limits well below those of other QSOs. The strong absorption seen in those few detected to date leads to an interpretation in terms of absorption of the x-ray emission by the same, outflowing wind and suggests that the column densities is at the high end of the quoted range.

Active Galaxies: Observing their Variability by Amateurs

Amateurs began to take an interest in observing the brighter active galactic nuclei (AGN) relatively soon after their discovery in the late 1960s, although a small number were observed as if variable stars prior to this. Leading amateurs have thus been observing the brighter AGNs for more than three decades, monitoring changes in their brightness. In addition, many recreational observers have tracked down these faint specks visually, especially 3C273 in Virgo, and marveled at the view, although less at their appearances than their extraordinary nature.

The first formal coordinated program for amateurs to monitor AGNs began in the UK in the late 1970s with the British Astronomical Association's Variable Star Section adding 3C273, NGC 4151 and Markarian 421 to its program. These were monitored visually as if faint variable stars. As telescopic apertures increased over the 1980s, more AGNs were added to the program. The Astronomer organization took up an interest and added this class of objects to its program, which remains active—observations are still being published in *The Astronomer* magazine monthly.

The potential for serious photographic work was realized in the late 1980s, the technique enabling the addition of several fainter examples that were too faint for most visual observers. This was a limited success, the difficulties of photographic patrolling limiting the popularity. It was not until the advent of the CHARGE-COUPLED DEVICE (CCD) and its availability to the amateur that the next boost to AGN observation was given. Of professional interest in amateur observations, there is no doubt—support and encouragement having been given by several international astronomers, CCDS, FILTERS AND CCD PHOTOMETRY FOR AMATEURS.

The broad aims of amateur AGN observations are threefold:

- to monitor apparent changes in brightness of accessible AGNs (see figure 1);
- to measure such changes and build up as accurate a light curve in visible wavelengths as possible;
- to alert professional astronomers to unusual activity, and anticipated activity of interest, and provide routine observations on a regular basis.

In order to monitor as many AGNs as often as possible, a coordinated program has been set up. There are currently over 20 AGNs available to the well-equipped amateur (some are listed in table 1). Although most are relatively faint, several are accessible to modest telescopes visually and all should be fairly straightforward targets for CCD users.

Observers are encouraged to make observations as regularly as skies and conditions allow. Almost all AGNs on the program are plotted in Uranometria 2000, although some have alternative designations from their more popular terms. However, use of coordinates should allow identification without difficulty.

Once located, the AGN's brightness can be estimated or measured, visually, photographically or with a CCD. Each has its merits and problems. In favor of a visual approach is the ability to observe several objects in the session; the results are rapidly obtained and the equipment is relatively inexpensive, although realistically a larger aperture is needed for such faint objects. However, the telescope need not be equatorially mounted. Set against these advantages are the problems of finding relatively faint objects from less than ideal sites, with problematic sky conditions, due to light pollution, moonshine, high cirrus and so forth. Experience in variable star work is essential. Inevitably, some observer bias occurs, although this can be compensated for, as with other variable star observations. Even if the AGN itself

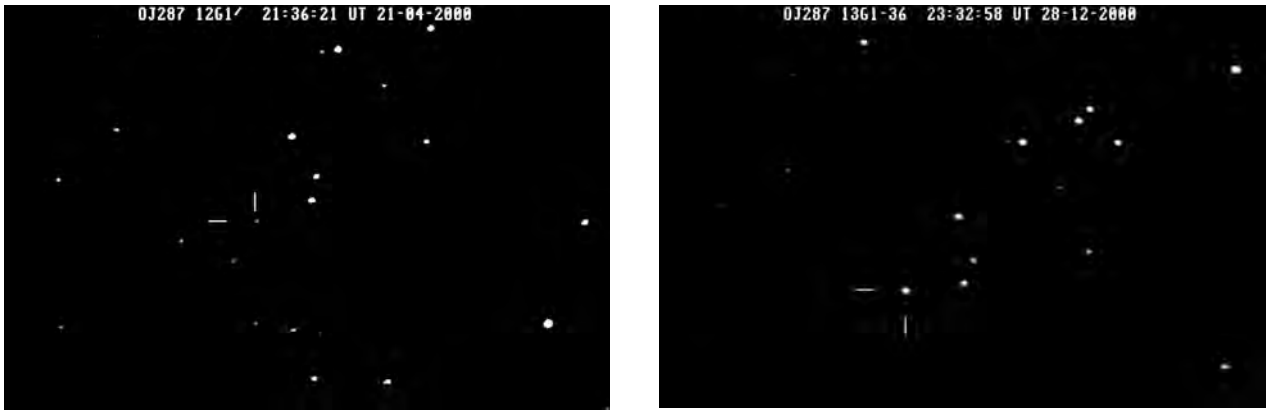

Figure 1. The dramatic rise in brightness of the very active BL Lacertae object OJ287 in Cancer is demonstrated in this pair of images. The image of 21 April 2000 shows the AGN to be at magnitude 16, that of 28 December 2000 at 14.5. Both images were obtained with a Meade LX 200, 250 mm *f*6.3 SCT and Starlight Xpress CCD camera; the April image was exposed for 80 s, that in December for 160 s. Neither was filtered.

poses no great problem, the fainter comparison stars may well be difficult. While the numbers of AGNs available are limited, there are still over a dozen to be observed by the owners of a 16 in telescope or larger.

Photography would seem to reduce some of these barriers. Fainter magnitudes can be reached so more active galaxies become available and the comparisons are more easily accessed. Personal bias is reduced and the results are easily displayed and reproduced. However, an equatorial or driven telescope becomes essential, raising the financial commitment. For the accurate results which the time and financial outlay deserve, standardization and formal measurement become necessary. This would require the observer to use a standard film (Kodak 103aB was recommended in the past, but it is difficult to obtain and other emulsions need to be tested). Also, filtered images are desirable, and for accurate magnitude estimates microdensitometric measures are ideal. Add to this the laborious process of photography itself and dark room work, and it is perhaps understandable that the photographic programs of the late 1980s never really came to fruition. The chance of discovering a nova or supernova is often adequate incentive to be involved in patrol work, but monitoring of an existing object year in, year out, is perhaps less enticing.

The CCD revolution seems be the answer to this. Images made with CCDs can go very deep, even with modest apertures. Many AGNs are available to owners of 10 in telescopes equipped with a CCD. Finding objects with smaller CCD chips was once notoriously difficult but modern GoTo facilities of many modern telescopes mean that the field can be confidently found and then the AGN identified from charts and imaged really quite rapidly and a measurement made.

Computer software is becoming more sophisticated and, with care, photometry accurate to around 0.1 magnitudes should be possible. The data are easily stored on disk and retrieved at leisure. Rapid comparison with a master image is possible to show any significant changes in brightness. This happy state of affairs is tempered by the need to spend a fair amount of money on equipment. In addition to a driven telescope, there is the CCD camera and computer plus necessary software. So to achieve the first meaningful CCD image of an AGN may cost the observer several thousand dollars.

Also, not all CCDs have the same sensitivities. Most have a red bias, which distorts the results, but different cameras have different profiles, so, for photometry to be really useful to the professionals, it is increasingly clear that filtration is needed (see CCDS, FILTERS AND CCD PHOTOMETRY FOR AMATEURS, FILTERS). It may ultimately be acceptable to use just B and V filters, even one of these. However, simple monitoring without photometry does not need filtered images and this can still be useful even if no filters are available to the observer. At present the majority of observations remain visual, with some CCD imaging, but, with more CCD users looking for serious projects, the emphasis may change.

AGNs offer a wonderful challenge to the serious amateur observer who wishes to contribute in their small way to an area of science in which the professionals welcome help, if provided carefully (see also ACTIVE GALAXIES: OBSERVATIONS). While not giving much in the way of spectacular views, AGNs feed the imagination in a way that is equally satisfying to the enquiring mind. The techniques are improving, the quality of results will become more refined and the study of the deepest of deep-sky objects is about to take off.

Active Galaxies: Overview

Defining an 'ACTIVE GALACTIC NUCLEUS' (AGN) can be difficult. The last two words are relatively simple, as an AGN is an energetic event which is *never* found anywhere in the universe except within the central parsecs of a galaxy. This is not surprising, because any dynamical friction should soon force any very massive compact object to settle down into the center of the galactic gravitational potential.

A GALACTIC NUCLEUS is said to be 'active' if it generates a 'substantial' (or detectable) amount of energy by processes different from those found anywhere else in galaxies. That is, the energy of the 'activity' is not produced by evolution of stars and interstellar matter. This definition is clean because it is theoretical. The actual observational task of identifying AGN can be messy, especially when the nonstellar activity is weak compared with the background of normal stellar processes, including birth and death. Classifying AGN meaningfully is harder. Understanding their physical nature is harder still.

The problems are further complicated because the nonstellar activity releases energy in many forms, and at photon wavelengths covering nearly the entire electromagnetic spectrum. Since observing instruments and methods differ markedly from one waveband to another, many overlapping wavelength-specific classification schemes and models have been proposed.

Not surprisingly, astronomers became aware of the more spectacular and luminous examples of AGN first. These nuclei were sufficiently luminous that they could outshine the entire galaxy in which they resided. They were also very distant, and it was often not possible, before very sensitive imaging had detected the surrounding galaxy, to distinguish their optical appearance from that of a star. This led to their designation as 'quasistellar' objects. Some of the first of these were also powerful radio sources, and the term was soon abbreviated to 'quasar', which now generally refers to all high-luminosity AGN (see QUASISTELLAR OBJECTS: OVERVIEW). Their unique nature became more obvious when studying their spectra, in almost any wavelength region.

These unique properties have now been found in active nuclei spanning an extraordinary range in luminosity[1]. There are only surprisingly subtle spectroscopic differences between a quasar with a luminosity of 10^{48} erg s^{-1} and what had previously been identified as a 'Seyfert galaxy nucleus' of luminosity 10^{42} erg s^{-1}. The evidence is overwhelming that these two astronomical categories must have a single common physical explanation. Thus today, hardly any distinction is made between 'quasar' and 'Seyfert 1 nucleus', as their main difference is (somewhat arbitrarily) in their luminosity. It follows that this overview of AGN should be supplemented by reading the accompanying chapters on quasars in this Encyclopedia.

[1] The vast range of AGN luminosities, much larger than what is seen in stars for example, is one of their outstanding features.

Understanding The Central Engine in AGN

There are several key ideas which are being used to organize and make sense of our large and growing observational information about AGN.

Unified Models

Since the earliest AGN studies, it was recognized that they can show strong observational differences in spite of many other similarities. Two characteristics seem to have a sufficiently bimodal distribution to justify using them to divide AGN into two pairs of classes: strong radio emission (which distinguishes radio-loud (RL) from radio-weak (RW) AGN) and broad permitted line emission (which distinguishes type 1 Seyfert nuclei from type 2). A more extensive discussion of these ideas is given in ACTIVE GALAXIES: UNIFIED MODEL and ACTIVE GALAXIES: VARIABILITY.

The majority of quasars are only moderately stronger radio sources than normal galaxies. (They are sometimes referred to as radio-quiet (RQ) AGN, although strictly speaking they do emit some radio flux so that RW is a more accurate description.) An important minority of quasars are well known for the beams of high-energy particles they accelerate. The radio emission from these jets is nearly always bipolar—a key indicator that the central engine can have axial symmetry. In many models, this jet–lobe axis is the spin axis of the central massive black hole. In the most dramatic subsample of RL AGN, the 'blazars' (loosely named after the prototype object BL Lacertae), the highly polarized, violently variable, steep red continuum was identified as nonthermal synchrotron emission. Blazar is an informal term used to encompass the prototypical nonthermal BL Lacertae objects (with very weak emission lines) as well as the optically violently variable quasars. Interferometric maps showed that the core-dominated radio emission generally had a one-sided jet, which often appears to be expanding at apparent transverse speeds several times larger than c. The most extreme of these objects appear to emit a substantial fraction of their energy in the gamma rays, and possibly even up to TeV energies. All of these remarkable (and manifestly nonstellar) blazar properties were soon understood as the result of viewing a relativistic jet (of electrons and either protons or positrons), which is emerging from the active nucleus close to our line of sight. This nearly 'pole-on' viewing angle produces several relativistic effects such as Doppler boosting of the 'beamed' synchrotron emission and a compression of apparent timescales which accounts for 'superluminal motion' without violating special relativity. The one-sided nature of the innermost jets is usually attributed to 'Doppler favoritism'. If there is currently an outflow in the opposite direction (which is predicted by some theoretical models, but not yet confirmed), it is invisible because Doppler de-boosting makes it thousands of times fainter.

An immediate consequence of the beaming explanation of core-dominated RL AGN is that more AGN with radio jets must be pointing away from Earth. These must be detectable by their isotropic emission (lines or extended radio lobes), as either lobe-dominated RL AGN, or perhaps

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

'radiogalaxies' (whose optical properties can be Sefyert 2s or even low-ionization emission line regions (LINERs)). The (unbeamed) emission lines may or may not be detectable but are harder to detect over the glare of the amplified nonthermal jet continuum.

These studies proved that the central engine in AGN (the RL ones, at least) have a strong bipolar symmetry which has been preserved over millions of years or more in the largest double-lobe radio sources. They also proved that the observational appearance of RL AGN can depend dramatically on our viewing angle. However, it is not yet certain how completely these same insights may be transferred to the majority of AGN, which are RW.

Broad permitted emission lines are usually taken as one of the defining characteristics of AGN. They arise from high-density photoionized gas. Their high ionization state and large velocity range both indicate that they arise in a 'broad line region' (BLR) relatively near the central engine. However, for every broad-emission-line AGN of a given luminosity (classified as a 'Seyfert 1'), there is at least one galactic nucleus which might otherwise be classified as a Seyfert, but which lacks broad line emissions and is classified as a 'Seyfert 2'. In the Seyfert 2s it is difficult or impossible to view the central engine, and its surrounding BLR, directly. In a minority of cases, strong evidence for the central engine is present, in the form of either a highly absorbed ($N_H \sim 10^{23}$ cm^{-2}) hard-x-ray continuum source or broad Balmer emission line wings seen in the spectrum of linearly polarized light.

Less direct evidence is the detection of fluorescent emission from the x-ray Kα line at 6.4 keV. In some Seyfert 2s, the very large equivalent width of this line (about an order of magnitude larger than in unobscured Seyfert 1s) is interpreted as being powered by a nuclear hard-x-ray source, virtually none of which is visible along our direct line of sight to the nucleus. A similar argument has been made from UV spectroscopy: adding up all the ionizing photons inferred from the UV continuum seems to be inadequate to account for all the Seyfert emission line flux detected, and especially for the infrared continuum also associated with the active nucleus. Assuming that the 2–10 μm continuum in Seyfert 1s and 2s is AGN energy that has been re-radiated by dust grains (see 'Reprocessing' section below), even more unseen nonstellar power is implied in Seyfert 2s. This 'energy deficit' argues for a high-energy power source which is present but not directly observable. However, these arguments are not conclusive. The energy accounting has many large uncertainties, and there are other plausible explanations of the Kα emission line that do not require the existence of a buried AGN x-ray source. Although it is difficult to obtain the very sensitive observations required for these tests, many thorough observations have failed to reveal any direct evidence of nonstellar continuum from a central engine. The more extended indications which are seen in these Seyfert 2s—narrow emission lines and radio sources—could have been produced by an AGN which 'turned off' centuries ago.

This raises an empirical question of whether most Seyfert nuclei can turn on and off over intervals of centuries. Although none has been observed for that long[2], very few complete Seyfert 2 $\leftrightarrow$ Seyfert 1 transitions have ever been seen, in decades of observing. Nonetheless, the unification assumption is that all of these Seyfert 2s harbor a currently active central engine, which is just extremely obscured.

Even if unification is generally correct, it simply requires optically thick gas, with a very large associated dust extinction, between us and the nuclei of Seyfert 2 galaxies. All we know is that this obscuring region must be large enough to cover up the broad emission line region, as viewed by a significant portion of the lines of sight to the central engine[3]. Similarly, dust grains must intercept a substantial portion of the central continuum and re-radiate it to produce the strong near- to mid-IR emission characteristic of both Seyfert 1 and 2 nuclei.

A popular special version of unification proposes that this absorbing matter is strongly nonspherical, and is distributed in a fat torus (of characteristic diameter parsecs to tens of parsecs) which is co-axial with the central engine. In the fat torus model the absence of obscuring material above the poles of the torus allows photons from the nuclear central engine to scatter into a clear line of sight to the Earth. The result would be a scattered nuclear spectrum—broad emission lines and nonstellar continuum—which we observe only in polarized light. Since the torus is supposed to be aligned with the axis of the central engine, the polarization E vector should be parallel to the radio axis. The latter is difficult to measure but is approximately parallel to the polarization in some of the best-measured Seyfert 2s. Further weak evidence for a preferred 'escape axis' for ionizing AGN photons is the loose tendency for extended ionized emission lines in Seyfert 2s to come from bipolar 'cones'.

In many Seyfert 2s, however, there is evidence (e.g. from HST imaging) that much obscuration instead occurs in galactic dust lanes. These are observed to be hundreds of parsecs in extent and not related to the central engine at all, except that they happen to block our view of it. It is still not clear how many, if any, Seyfert 1s and 2s really harbor complete fat tori wrapped around their central engines.

Thermal emission from an accretion flow

The enormous energy outputs from very small volumes that are observed in luminous quasars are believed to be generated by black hole accretion. To avoid greatly exceeding the Eddington limit, the accreting black holes must have masses of several 10^6–10^9 Suns. However, the conversion of the gravitational potential energy of the inflowing matter into radiation is not at all efficient if there is a purely radial infall. Also, general considerations of

[2] However, NGC 1068 = Messier 71 might, in a bright Seyfert 1 state, have been marginally visible to the naked eye.

[3] Since the space density of Seyfert 2s is somewhat higher than that of Seyfert 1s, this covering fraction of obscuration must be larger than 50%

the angular momentum of gas deep in a galactic nucleus strongly suggest that the accretion flow must end up rotating rapidly as it nears the black hole. Then it can only accrete and power the AGN if it experiences friction. Although not yet well understood, this crucial process transfers angular momentum outward, allowing the black hole to be fueled. This accretion is accompanied by a large release of radiative energy, which powers the AGN. The fact that angular momentum is important in the accretion flow is supported by the observation that the central engine is bipolar. Its symmetry axis is naturally identified with the spin axis of the accretion flow and is the direction of the most likely outflows. There is also observational evidence that we observe directly the radiation emitted thermally from this accretion flow, as it spirals into the black hole.

One of the defining characteristics of the spectrum of the central AGN continuum source is a broad hump which appears to peak somewhere in the UV. This inflection, referred to as the 'ultraviolet excess' or 'big blue bump', often contains the largest portion of the total AGN luminosity.

The main arguments in favor of a thermal origin of this blue–UV continuum are as follows.

- *Its spectral shape*. The broad peak in the UV can be fitted by a sum of thermally emitting regions spanning a range of temperatures, centered on ∼30 000 K. In a simple optically thick accretion disk, such as would be expected for most luminous AGN, the thermal temperature of the accretion flow is proportional to $r^{-3/4}$. With the inclusion of relativistic corrections, the sum of thermal emission from rings of varying radii adds up to a spectrum with a broad peak which is flat in flux density units (F_ν = constant) and has a high-frequency turn-over. Models which treat the disk as a sum of blackbodies provide remarkably good fits to all the optical–UV spectral energy distributions observed in AGN.
- *Its peak frequency*. The effective temperature in an accretion flow is approximately determined by the balance between the gravitational potential energy released as a result of viscous accretion and the radiation emitted[4]. In a thin disk this condition is $T_{\rm accretion} = (3GM_{\rm bh}\dot{M}/8\pi r^3)^{1/4} = (30\,000\,{\rm K})\,(M_8)^{1/4}(L/L_{\rm Eddington})^{1/2}$. The luminosities and peak frequencies observed in the continuum spectra of Seyfert 1 nuclei and quasars are consistent with the equilibrium temperatures predicted for disk accretion. The required respective mass infall rates are ∼ several per cent and ∼ tens of per cent of the Eddington limit for the inferred black hole masses[5].

Even for the highest plausible values of viscosity (corresponding to the most rapid inflow), the accretion flow is still expected to be very opaque to electron scattering and is probably effectively optically thick ($\tau_{\rm effective} = (\tau_{\rm es}\tau_{\rm ff})^{1/2} > 1$). The best observational evidence for this is the high inferred emissivity of the gas emitting the UV continuum. It is true that optically thin thermal models can also fit the observed optical–UV continuum. The characteristic temperatures of the bremstrahlung emission would have to be 100 000 K or higher, because free–free emission peaks at around $\nu_{\rm thin} = kT/h$, rather than the higher value for a Planck function: $\nu_{\rm thick} = 3kT/h$. EUV emission lines that might be expected from such a luminous plasma have not yet been seen. The most serious difficulty with the free–free hypothesis is explaining how the very large continuum luminosity of a quasar is emitted from a small area. For the UV brightness of a luminous quasar such as 3C 273 to vary on timescales of months requires a small thermally emitting region with high emissivity, so high, in fact, that the emitter must have an optical depth exceeding 1. At this point the emitted spectrum will resemble optically thick emission more than an optically thin $L_\nu \propto \exp(-h\nu/kT)$ spectrum.

The principal limitations or incompletenesses of the thin accretion disk model are the weakness of any observed spectral feature at the Lyman limit, the low amount of linear polarization, and multiwavelength monitoring evidence for reprocessing, discussed in the next section. The spectrum emerging from an accretion disk at a given radius depends on the vertical structure of the disk 'atmosphere'. A ring of an accretion disk differs radically from the atmosphere of any star, but it has recently become computationally feasible to make realistic non-LTE models of the emergent spectrum. Many UV-emitting rings of the disk have low enough temperatures that they should still contain some fraction of neutral hydrogen. This should lead to a sharp increase in the bound–free opacity across the Lyman edge. Some models predict that this will lead to a spectral jump, with the flux above the Lyman limit either higher or lower than the flux below it. These discontinuities are not in general observed. Opacity in the accretion disk is probably dominated by electron scattering. A pure electron scattering atmosphere of infinite optical depth viewed at an average inclination of $\cos i = 0.5$ should emit a thermal continuum which is linearly polarized by almost 3%. The position angle of the electric vector should be parallel to the projected major axis of the disk—perpendicular to the disk spin axis. However, observations show that most AGN polarizations are under 0.5% in the UV[6]. Also, in those cases where a radio 'axis' can be defined, it is not generally perpendicular to the E vector of the polarized flux. The greatest uncertainties in this test are the assumptions that the disk surface is perfectly flat and that magnetic fields in the disk are small enough to avoid causing appreciable Faraday rotation.

One deficiency of the simple thin accretion disk models that may be related to these observational conflicts

[4] In fact the viscous torques transport some of this potential energy outward, but most of it should eventually emerge as photons.

[5] Above the Eddington accretion rate, the disk is expected to thicken somewhat, but its overall observational properties may not change very greatly.

[6] However, the linear polarization appears, mysteriously, to increase dramatically, at rest wavelengths shorter than ∼800 Å.

is the likely presence of a hot optically thin corona above the photosphere of the disk surface. The fast electrons in this low-density gas can Comptonize the thermal photons escaping from the dense disk, modifying their spectrum and polarization.

Reprocessing

In the simplest accretion disk models, all of the thermal energy emitted by the disk was derived directly from gravitational potential energy, which is transported outwards by viscous torques. We know, however, that AGN also emit up to 10% or 20% of their luminosity at x-ray frequencies. These photon energies are too high to be readily explained by the thermal accretion disk paradigm, and their flux near the center is very high. Depending on the geometry, some of these x-rays could be re-absorbed by the optically thick accreting gas before they manage to escape. Some absorption of x-rays is probably required to explain the 'Compton reflection' hump observed around 10–30 keV (see discussion in ACTIVE GALAXIES: OBSERVATIONS). Reprocessing of x-rays is presumed to be the origin of the strong Fe Kα emission line seen in many AGN.

Reprocessing of photons at radii much larger than where they originated tends to degrade the energies of the photons that escape. In the simplest case, where the equilibrium blackbody temperature of the reprocessing matter drops as $T_{\rm equil} \propto L^{1/4} r^{-1/2}$ (where L is the luminosity of the central point source), the resulting thermal continuum spectrum tends to steepen to a slope of $L_\nu \propto \nu^{-1}$. Some reprocessing must occur; the main questions are: where and how much?

The first question is easy to answer assuming the absorbed photons are thermalized: the radius of the reprocessing determines $T_{\rm equil}$ of the emerging radiation, which should peak somewhere around a few $h\nu/kT_{\rm equil}$. The second question can be answered if we can measure the fraction of the total amount of energy which has been absorbed. If we assume that the reprocessing matter (gas, and dust if $T_{\rm equil}$ is under 1000 K) is opaque to incoming high-energy photons, then the energy budget can tell us its total sky covering fraction, i.e. the fraction of the sky as seen by the central continuum 'point source' which is covered by absorbers. By definition, the reprocessed luminosity cannot exceed the luminosity of the original high-energy continuum source in the center. It is actually unlikely that their luminosities would even be equal, because that would imply that 100% of the lines of sight to the center are blocked, in which case we should not be able to see it directly at all.

The best observational proof of reprocessing is to show that time variability in the primary waveband is then duplicated by the same flux changes at the reprocessed wavelength, except with a lag. The delay time in this 'reverberation' should equal the amount of time it takes light to travel across a region whose radius is given by the value of $T_{\rm equil}$ expected for the wavelength of the reprocessed continuum.

The best evidence for reprocessing is for the near-infrared continuum, which caries a substantial fraction (20% or more) of the total energy budget of most AGN. In several cases, simultaneous monitoring of the near-infrared and optical or UV continua has shown the expected correlated brightening and fading. The delay of the infrared light curve with respect to the light curve at shorter wavelengths is consistent with thermal re-emission by hot dust grains within a light year (or even light month) of the central powerhouse. The response is mostly from the hottest grains, surviving at just below their sublimation temperature of around 1000–1500 K. The distance from the central engine at which dust equilibrates to this temperature is proportional to the square root of the central luminosity, explaining the range of expected dust reverberation radii.

Less decisive evidence suggests that some of the optical continuum, and possibly even the UV continuum, in some Seyfert 1 nuclei, may have a measurable contribution from reprocessed x-rays. This is in several well-sampled x-ray and optical–UV light curves where a correlation and lag were detected. The lags are so small that they imply that the influence of the high-energy photons propagates outward to the low-energy emitting region at very high speed. The lags are consistent with this speed being c, as it should be if the influence is carried by photons which are then reprocessed. However, the variability of the x-rays (in other galaxies, as well as in some of these Seyfert 1s at other epochs) is often not correlated with changes at other wavelengths, casting doubt on whether much of the optical–UV light in most AGN is actually reprocessed from the x-rays.

Influence of host galaxies

Galaxies with Seyfert nuclei account for only a fraction of all galaxies. This estimation is complicated by the difficulty of identifying AGN with very low nonstellar luminosities. For example, many galaxies have weak emission line spectra with line ratios intermediate between those of H II regions and Seyfert nuclei, which are referred to as 'LINER' galaxies. Although these LINER spectra can be explained by fast shocks, they might still be included as having active nuclei (and the case is getting stronger for at least some of the members of this heterogeneous class). If so, then it is even possible that most galaxies are in some sense 'active'. The most definitive evidence of a truly nonstellar nucleus is probably a compact central source of hard x-rays, preferably variable. However, this would be obscured by gas with a column density of 10^{25} cm^{-2}, which is optically thick to Thomson electron scattering of hard x-rays. It may not be entirely surprising that, outside of the nucleus, the 'host galaxies' themselves hardly appear different from galaxies lacking obvious AGN. A very powerful AGN can have some limited effects on the interstellar medium of its galaxy, such as ionizing it, shocking and compressing it, and in some special cases even inducing stars to form, near an outflowing jet for example.

A deeper mystery is what properties of the galaxy cause the AGN in the first place. The two most obvious ones are the origin of a massive black hole and the ability to provide enough fuel close into the nucleus to 'feed' it. The formation of a massive black hole probably requires the dynamical collapse of a dense star cluster in the dense center of a galaxy. As the first dense structures to come together in the young universe are thought to be proto-galactic bulges, there is some weak theoretical motivation for associating massive black holes with modern-day bulges. The dramatically higher (by orders of magnitude) proper space density of luminous AGN in the early universe requires that many seemingly 'normal' galaxies today must once have harbored an AGN central engine. If it was a black hole, it should still be present, and may be detectable by its gravitational acceleration of stars and gas within a few hundred parsecs. (The gravity of a black hole of mass M_{bh} dominates out to a radius of roughly GM_{bh}/σ^2 where σ is the characteristic velocity dispersion in the stellar system.) This region is small enough that it can only be resolved optically in the nearest galaxies with the best spectrographs (Hubble Space Telescope, or ground-based telescopes with excellent seeing). The kinematic search for nearby massive black holes (using Doppler spectroscopy to measure orbital velocities around the nucleus) is still in its early phases, with less than a few dozen detections (see also SUPERMASSIVE BLACK HOLES IN AGN). These provide a tentative suggestion that the central black hole mass might correlate linearly with the total galactic bulge mass, with a normalization constant of about half of a per cent. However, this claimed correlation may have enormous scatter or may not even prove significant when an unbiased sample of galaxies is studied intensively and upper limits to M_{bh} are all included.

In the near future, the set of galaxies with reliable central black hole masses has unfortunately very little intersection with the set of active nuclei for which mass estimates can be attempted. This is because the latter is measured from nonstellar emission, while the former comes from nonactive emission. If one of these dominates and is easily studied, the other will not be well measured. Nonetheless, the current evidence on black holes, mostly in nonactive galaxies, suggests that the key potential ingredient for the central engine—the massive black hole—may be present in many or even most galaxies. The fact that most of them today are not Seyferts must then be attributable to a lack of fuel.

Even assuming the most efficient known models, black hole accretion disks, the energetics of the most powerful quasars require tens of solar masses per year to be supplied to the central parsec of the galaxy. To reach such a small radius, the fuel—probably gas—must lose essentially all of its orbital angular momentum. On theoretical grounds, the required torques may be provided by distortions and asymmetries in the gravitational potential of the host galaxy, such as bars (see GALAXIES: CLASSIFICATION; FORMATION)[7].

Unfortunately, it has been difficult to show much association between the presence of close companions and an active nucleus. Also there is no correlation between bars and Seyfert activity. One possibility is that bars and/or encounters only enhance nuclear activity with a great delay (of perhaps a billion years), since it could take that many orbits for the gas to eventually fall down into the nucleus. One possible indication of this is the finding that Seyfert galaxies are more likely to show rings, which may be long-lived relics of bars that have already dissipated. A possible connection between Seyfert activity and earlier star-formation activity is the observation that the disks of Seyfert host galaxies tend to have higher surface brightnesses than those of non-Seyfert galaxies.

Future prospects

Understanding AGN is a seriously data-limited problem. Its typical variability proves that the central engine is not in a steady state. We can turn this into an asset in trying to understand it, but only if we can obtain extensive, nearly continuous time histories of the emission from individual AGN. Beyond limited time sampling, the two most serious observational limitations have been the following.

- *Inadequate observations of many of the wavelength regions where AGN emit*. AGN are the most broad-band emitters in the universe, and many of the wavelengths at which they emit are blocked by the Earth's atmosphere, or more fundamentally by H I absorption in the intergalactic medium (shortward of a rest wavelength of 912 Å).
- *Inadequate spatial resolution*. The largest relevant scales for most of the interesting and extreme AGN phenomena are of order 10 pc or even less.

Fortunately both of these limitations are rapidly easing with the advent of new detectors and observatories. The critical AGN observations during the next decade will benefit from new and planned space observatories and new ground-based techniques such as interferometry. Also, the ultimate in spatial resolution is becoming available by using intensive monitoring to detect light-travel delays, as in reverberation mapping.

Matthew Malkan

[7] Two controversial observational claims may support applying this idea to star formation. One is that spiral galaxies with bars are more likely to have higher rates of recent star formation than unbarred spirals. Another is that close galaxy encounters, which also apply an $n = 2$ mode perturbation to the galactic potential, are also associated with elevated rates of star formation.

Active Galaxies: Unified Model

Objects known as 'ACTIVE GALACTIC NUCLEI' (AGN) can be grouped into a wide variety of phenomenological subclasses that have many overlapping or similar properties. The first known 'active galaxies' were the high-surface-brightness spiral galaxies identified by Carl Seyfert in 1943. Almost two decades later, the first radio surveys of the sky led to the identification of other objects (radio galaxies, such as Centaurus A, and quasars, such as 3C 48) that we now also think of as active galaxies, though the similarities between the radio sources and Seyfert's spirals were not obvious at the time of discovery. Early failure to recognize the underlying similarities of these objects was largely because the different identification techniques used isolated extreme members of the active-galaxy population: radio-source identifications tended to yield relatively high-luminosity, high-redshift quasars (short for 'quasistellar radio sources'), often members of the 'blazar' class (see BL LACERTAE OBJECTS), in which beamed emission from a relativistic jet dominates most of the observed spectrum. On the other hand, identification of bright galactic cores led to identification of the spatially common, relatively low-luminosity radio-quiet Seyfert nuclei (see ACTIVE GALAXIES: OBSERVATIONS).

It was only in the late 1960s and 1970s that optical, color-based detection criteria (either multiple-color broad-band photometry or low-dispersion spectroscopy) began to yield large enough samples of both high- and low-luminosity AGN that the fundamental similarities began to become clear. Indeed, color-based selection of AGN led to the discovery that most high-luminosity AGN are not of the 'radio-loud' quasar variety, but are 'radio-quiet' sources that came to be known as 'QUASISTELLAR OBJECTS' (QSOs). Despite the emerging similarities between Seyfert galaxies and QSOs, important differences among types of AGN were also identified, leading to a broad and fairly complex AGN taxonomy (see ACTIVE GALAXIES: OVERVIEW).

Comparison of various types of AGN should help us understand which phenomena are fundamental to nuclear activity and which are somehow incidental or secondary. In some cases, as we will see below, differences among various types can be used to infer source structure on scales too small to resolve directly. Some of the important questions that arise in this context include the following. Why are only ∼10% of active galaxies radio-loud? Why are broad emission lines weak or absent in the UV–optical spectra of BL Lac objects? Why do some Seyfert galaxies have no broad emission lines?

Unification

Principles

In attempting to explain the differences among various classes of AGN, our goal is to explain the widest variety of phenomena using the simplest model that is consistent with the data. A simple hypothesis to explain much of AGN phenomenology is that the differences among various types of AGN arise from orientation dependence; simply put, we try to 'unify' various AGN types in terms of a single basic source structure whose appearance to the observer depends strongly on viewing angle. There is indeed abundant direct evidence that AGN have axisymmetric structure and thus radiate anisotropically; the observable properties of a particular source will thus depend on the location of the observer. It is therefore postulated in such 'AGN unification' schemes that the different appearance of one class compared with a second is the result of viewing the same type of object at a different angle. Properties that may depend on viewing angle and may so contribute to intrinsic anisotropy in these sources include absorption by dust or optically thick gas in any non-spherically symmetric distribution and relativistic motion which leads to Doppler boosting of the emission which peaks in the direction of this motion. Unification schemes incorporating one or both of these intrinsic source properties seek to explain at least part of the wide diversity we observe in AGN in terms of these differences in viewing angle. There are several unification schemes seeking to unify two or more classes of AGN that have met with some degree of success; several of these are outlined in table 1 and will be described below.

Table 1. Possible simple unifications.

Radio properties	Orientation	
	Face on	Edge on
Radio quiet	Seyfert 1	Seyfert 2
	QSO	ULIRG?
Radio loud	BLRG	NLRG
	Core dominated	Lobe dominated
	BL Lac	FR I
	Quasar–OVV	FR II

An obvious key element in any unification scheme is proof of its plausibility. If we hypothesize, for example, that some specific type of AGN (say, BL Lacertae objects) are members of some particular broad class or 'parent population' (say, Fanaroff–Riley class I radio sources[1]), then the space density of the subclass must be consistent with the space density of the parent population times the probability of observing a member of the parent population at a suitable orientation. Determining the space density of the parent population is often a difficult task in itself and must rely on source identifications based on some property which is supposed to be isotropic. Hard x-ray emission, for example, is thought to be emitted approximately isotropically by non-blazar AGN, and in principle hard x-ray emission may be the best way to

[1] Fanaroff and Riley showed that extended radio sources can be divided into two luminosity classes that have different morphologies. Class I (FR I) are less luminous sources, $L_\nu(1.4\,\mathrm{GHz}) \lesssim 10^{32}\ \mathrm{erg\ s^{-1}\ Hz^{-1}}$, that are brightest in the center with decreasing surface brightness towards the edges. Class II (FR II) sources are the more luminous sources, which are limb-brightened or have non-central regions of enhanced emission.

find a homogeneous sample of AGN. Indeed hard x-rays are probably the *sine qua non* of an active nucleus. In practice, however, relatively low hard x-ray sensitivities have limited detection of AGN to those that are relatively nearby and thus apparently bright. For radio sources (which includes blazars), radiation from the optically thin extended lobes is assumed to be emitted isotropically and in principle can be used to identify objects with intrinsically similar luminosities.

The basic model

The current AGN paradigm is built around an axisymmetric central engine that consists of an accretion disk surrounding a supermassive ($\gtrsim 10^6 M_\odot$) black hole (see SUPERMASSIVE BLACK HOLES IN AGN). The UV–optical continuum emission is supposed to arise primarily in the accretion disk. Bi-directional relativistic jets emerge from this system along the disk axis, emitting Doppler-boosted radiation via synchrotron and inverse Compton mechanisms. Both the jets and the accretion disk structure are thought to contribute to the x-ray emission. The broad emission lines (whose width can be characterized in terms of the full width at half-maximum, FWHM $\approx$ 1500–10 000 km s^{-1}) that are so prominent in the UV–optical spectra of AGN are produced in relatively dense (electron densities $n_e \approx 10^{11}$ cm^{-3}) gas clouds at distances from the black hole of several hundred to several thousand gravitational radii ($R_{grav} = GM/c^2$, where M is the mass of the central black hole, G is the gravitational constant, and c is the speed of light). On parsec scales, this entire system is embedded in a dusty torus that is opaque over most of the electromagnetic spectrum; this torus plays a key role in AGN unification models since it shields both the accretion disk, broad-line region, and inner jet structure from the direct view of external observers in the torus plane. The torus absorbs radiation from the central source and re-emits this energy in the infrared. Narrow emission lines (FWHM $\lesssim$ 300–800 km s^{-1}) arise in low-density clouds at the torus scale and beyond, mostly driven by radiation from the central source, and therefore largely constrained to lie along the system axis.

AGN unification schemes

Seyfert types

Probably the best known unification scheme is that between the two types of SEYFERT GALAXIES. In the mid-1970s, Khachikian and Weedman found that Seyfert galaxies fell into two spectroscopic classes, those with both narrow and broad emission lines (type 1 or Sy1) and those with narrow lines only (type 2 or Sy2). The narrow-line spectra of types 1 and 2 are statistically indistinguishable from one another, so Sy2s seem to be Sy1s without the broad lines. Moreover, Sy2s are typically less luminous than Sy1s by about 1 magnitude in the optical part of the spectrum. This led to unification hypotheses in which Sy2s are intrinsically Sy1s whose continuum and broad-line emission is attenuated in the direction of the observer. While simple and attractive, this hypothesis had two major difficulties: first, why is the AGN continuum source extinguished by only a factor of a few, but the broad lines by an apparently larger factor? Second, the shape of the Sy2 continuum does not look like a dust-attenuated Sy1 AGN continuum, i.e. Sy2 continua do not appear to be highly reddened by passage through a medium in which the absorption or scattering cross-section decreases with increasing wavelength.

A breakthrough occurred in the early 1980s when Antonucci and Miller found that the polarization spectra of some Sy2 galaxies such as NGC 1068 (see the articles on NGC 1068 and POLARIZATION IN ACTIVE GALAXIES) contained broad emission lines like those seen in Sy1 spectra. At least some Sy2 galaxies contain broad emission lines, but with their strength greatly reduced such that they are dominated by the continuum and narrow lines except when viewed in polarized light. Since the most common cause of polarization is scattering of light by either dust or electrons, this observation led to an interpretation of Sy2 galaxies as edge-on Sy1 galaxies where optically thick material in a flattened, disk-like geometry obscures our direct view of the broad emission-line region, as described above and illustrated in figure 1. The broad lines are visible in polarized light when they are scattered into our line of sight by dust or electrons above and/or below this material. In the case of NGC 1068, the AGN continuum light is $\sim$16% polarized, independent of wavelength through the UV–optical spectrum, which argues that the scattering mechanism is electrons rather than dust, since the Thomson scattering cross-section is wavelength independent while dust scattering is strongly wavelength dependent. In other polarized Sy2s, however, there is evidence that dust scattering also plays a role. The polarization spectra of these Sy2s also show that the emission lines are more strongly polarized than the continuum. There is apparently a second unpolarized component to the featureless AGN continuum that constitutes some 60–90% of the total continuum and has approximately the same spectral shape as the polarized component. The origin of the unpolarized component is unclear, although it may arise from free–free emission in the scattering region itself. In any case, the existence of this component explains why the non-stellar continuum in Sy2s is not as thoroughly suppressed as the broad lines.

Predictions of the relative numbers of each class provide an important test but are very sensitive to assumptions such as the opening angle of the torus and the angular dependence of the luminosity. Within these limitations the relative numbers are consistent with expectations and indicate torus semi-opening angles of $\sim 60^\circ$. As more Sy2 galaxies and lower-luminosity AGN, such as LINERs (low-ionization nuclei emission region galaxies), are observed in polarized light, more edge-on Sy1 galaxies are discovered. It is not yet clear, however, whether all AGN, or even all Seyfert galaxies, fit into this scheme. Current studies show a detection rate for polarized broad lines in Sy2 galaxies of $\sim$50%, implying that many Sy2 galaxies either do not possess a scattering region or that they have no broad-line region.

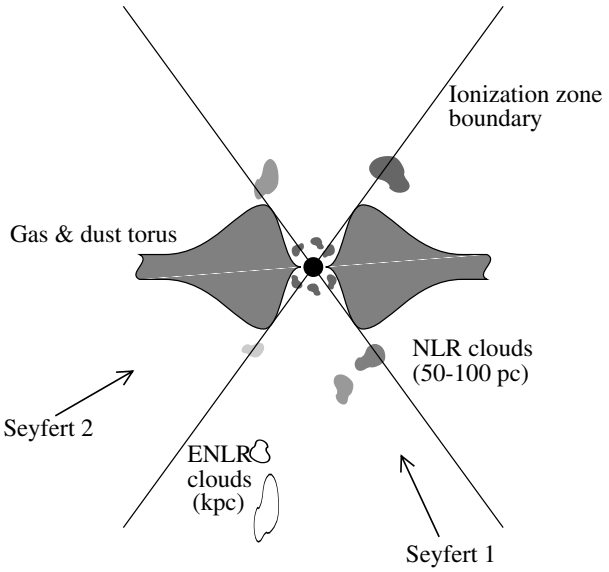

Figure 1. The conceptual scheme for unification of Sy1 and Sy2 galaxies (not to scale) with an optically thick torus of cool material surrounding the continuum source (central circle) and the broad emission-line region (BLR, small 'clouds' surrounding continuum source). From Peterson (1997), originally from R W Pogge.

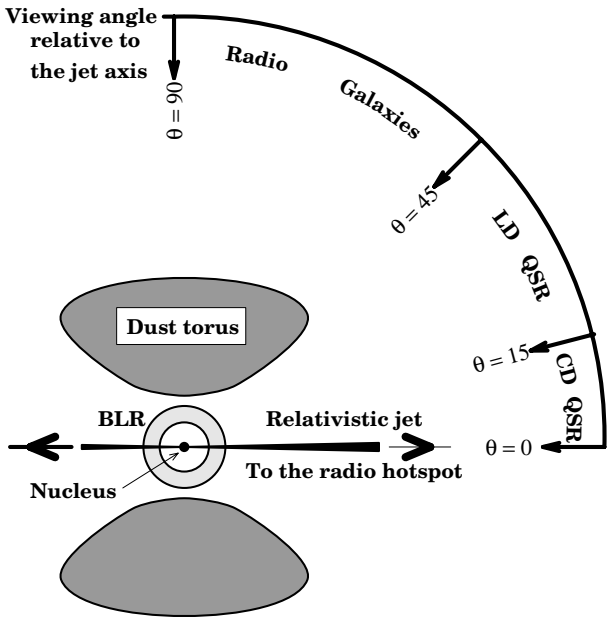

Figure 2. A scheme for unification of strong-line (BLRG, NLRG and quasars (QSR)) radio sources. Compare with figure 1 (rotated through 90°). Here the BLR is shown as a shaded shell around the continuum source (circular spot). From Kembhavi and Narlikar (1999), originally from R Athreya.

X-ray observations of AGN also generally support this unification picture. The x-ray luminosities of Sy2 galaxies are lower than those of Sy1 galaxies. Moreover, Sy2 galaxies have significantly larger amounts of soft x-ray absorption, corresponding to equivalent columns of neutral hydrogen, $N_{\rm H} \approx 10^{22-23}$ cm^{-2}, in comparison with $N_{\rm H} \approx 10^{20-21}$ cm^{-2} for Sy1 galaxies. This is consistent with our line of sight through the AGN being through an optically thick torus of cold material.

A similar unification scheme probably explains the difference between 'broad-line radio galaxies' (BLRGs), which might be described to first-order accuracy as radio-loud Sy1, and 'narrow-line radio galaxies' (NLRGs), which have Sy2-like optical spectra. A schematic of the geometry to unify the strong-lined radio galaxies is shown in figure 2.

A remaining puzzle is the apparent lack of an equivalent bifurcation in the higher-luminosity QSOs; there is no generally accepted class of 'QSO 2s' which would correspond to the low-luminosity Sy2 galaxies. The most likely candidates for dust-obscured QSOs are near IR-selected AGN, some of which do show broad lines in polarized light, or the cooler, ultraluminous IR galaxies (ULIRGs) whose emission may be predominantly due to reprocessing by cool dust. At the present time, it is clear that some ULIRGs harbor unseen AGN, but others are powered by starbursts, not by *bone fide* AGN.

Core- and lobe-dominated quasars and radio galaxies

As noted earlier, only about 10% of AGN are strong radio sources. Within this subset, there is a wide range of radio morphological structures (see also RADIO EMISSION FROM BINARY STARS) from classical double-radio sources on scales as large as megaparsecs to small, core-dominated sources with little or no extended structure. The core-dominated sources commonly show superluminal motion indicating relativistic outflow velocities close to our line of sight (see SUPERLUMINAL MOTION). Classical double sources often have one-sided, highly collimated jet structures extending from their compact core towards one of the extended lobes. The one-sided nature of the jets can be understood in a relativistic scenario whereby an approaching jet and an oppositely directed receding jet are respectively Doppler boosted and dimmed by relativistic effects. Thus both of these properties are consistent with relativistic jets originating in the core of a radio source and feeding the outer lobes. This suggests that the main variable governing the observed morphology of a radio AGN is its orientation to our line of sight. In core-dominated sources we are looking down the relativistic jet, while in double sources the jet is projected onto the plane of the sky.

A prime test of this unification scheme is to compare the relative numbers of core- and lobe-dominated sources and the distribution of projected sizes for radio AGN with the model predictions. The jet is highly collimated so that the main uncertainty is the amount of boosting due to the relativistic motion in the jet, determined by the bulk Lorentz factor $\gamma = (1 - V^2/c^2)^{-1/2}$, where V is the outflow velocity and c the velocity of light. It is thus difficult to match core- and lobe-dominated objects in intrinsic luminosity and so ensure that relativistic beaming effects

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

are not a factor in any comparative studies. In general, these studies show that there are too many core-dominated sources compared with the lobe-dominated ones and that the former are too large when de-projected based on the observed Lorentz factor. There is also a lack of two-sided jets, i.e. sources aligned with the plane of the sky. Many of these inconsistencies can be solved if the highly luminous FR II radio galaxies (BLRGs and NLRGs) are included in the unification. In this case, the lobe-dominated, radio-loud QSOs are viewed at an angle intermediate between those of the radio galaxies, and the QSOs and the larger size of the radio galaxies matches that of the de-projected core-dominated sources. However this solution introduces a new problem, namely that the narrow [O III] $\lambda\lambda$ 4959, 5007 line emission is significantly (by a factor of 4–10) weaker in radio galaxies than in quasars, which requires that these lines also be emitted anisotropically for unification to work. The similar strength of the lower ionization [O II] λ 3727 line in the two classes supports this scenario since it originates at larger distances from the AGN core and so is expected to be emitted more isotropically.

Within the context of this orientation picture, the inclination of a radio source is related to the ratio of core to lobe luminosity, largely as a result of the relativistic boosting of the core luminosity. This parameter, known as core dominance R, can then be used to study the dependence of other parameters on inclination. For example the widths of the broad Hβ and C IV emission lines indicate that face-on (core-dominated) objects tend to have relatively narrow broad lines (FWHM $\approx$ 1000–5000 km s^{-1} while edge-on (lobe-dominated) have a wider range of line width (FWHM $\approx$ 1000–10000 km s^{-1}). This result suggests that the orientations of the broad emission-line region and the obscuring torus are similar.

Blazars and radio sources

With the recognition that blazar emission originates in relativistic jets towards the observer, radio galaxies with jets in the plane of the sky presented themselves as candidates for 'misaligned' blazars. Blazars themselves fall into two distinct categories, 'BL Lacs' and 'optically violent variables' (OVVs), and these seem to be drawn from different parent distributions of radio galaxies. The primary distinction between OVVs and BL Lacs is that OVVs have strong UV and optical emission lines so their UV–optical spectra resemble those of non-beamed AGN, whereas in BL Lacs other spectral features are swamped by the emission from the jet. OVVs also have higher luminosities and higher inferred Lorentz factors than BL Lacs.

It is possible to make a fairly convincing argument that BL Lacs reside in FR I radio galaxies. By disregarding the spatially unresolved blazar core emission and considering only the luminosity of the 'extended' radio source (presumably the 'lobes' seen along their axis), it is found that FR I galaxies and BL Lacs have comparable radio luminosity, supporting the notion that they are drawn from a single population. The luminosity functions and space densities are also consistent with unification of these two types of object. It should be mentioned at least in passing that BL Lacs themselves have been sometimes divided into radio-selected and x-ray-selected subcategories, and on average sources in these categories tend to have spectral energy distributions that peak, not surprisingly, at low and high frequencies, respectively. Recent work suggests that these are not, in fact, distinct classes, but rather represent the extremes of a continuous distribution in peak wavelength for the entire class of BL Lacs.

The more luminous FR II radio galaxies afford a plausible parent population for OVVs. Compared with the FR I–BL Lac unification scheme, this is more difficult to demonstrate, at least in part because the FR II population is relatively less homogeneous.

'Grand unification': radio-loud and radio-quiet AGN

One of the longest-standing questions in AGN astrophysics is why, despite being optically similar, a small minority ($\lesssim$10%) of AGN are radio loud while the remainder are radio quiet? Any unification scheme that can explain the difference between these two major classes of AGN would go a long way towards explaining the AGN phenomenon in general, and is therefore sometimes referred to as 'grand unification'. There is a clear dichotomy between the radio-loud and radio-quiet sources; for a given IR through soft x-ray luminosity, the radio-loud AGNs are 2–3 orders of magnitude more luminous in the radio than the radio-quiet objects. There are very few objects of intermediate radio luminosity so the distribution of radio power relative to power at shorter wavelengths is clearly bimodal. In other words, the evidence clearly points to two distinct AGN populations defined by relative radio luminosity.

An early suggestion advanced by Scheuer and Readhead was that the radio-loud and radio-quiet objects constitute a single population in which the radio-louds represent the sources with axes oriented towards the observer. This failed, however, to account for the lack of extended radio emission in the radio quiets.

Radio-quiet and radio-loud AGN differ in other respects. Radio-loud AGN are, on average, about a factor of 3 brighter in the mid-energy x-rays (0.2–3.5 keV) with somewhat flatter spectral slopes (i.e. relatively more high-energy photons). This is thought to be due to the presence of beamed X-ray emission related to the radio-emitting jet and provides evidence for the unification of core- and lobe-dominated radio-loud AGN discussed above. However, the difference in x-ray spectral slope would be hard to account for in a grand unification scenario.

The emission-line spectra of the two types of object also show differences, at least in a statistical sense (e.g. stronger optical Fe II blends, weaker narrow lines and narrower broad lines in the radio-quiet objects).

Until relatively recently it was believed that broad relatively blueshifted absorption-line features that are

indicative of mass outflows are only found in radio-quiet AGN; it is now clear that these also occur in radio-loud AGN, although at the present time it appears that the flows in radio-loud objects have relatively lower terminal velocities. The outflowing material responsible for the absorption is generally thought to be accelerated away from the surface of the torus and so expected to be present at certain orientations in both radio-loud and radio-quiet AGN.

No satisfactory explanation for the differences between radio-loud and radio-quiet sources has yet emerged. Although hard to understand, it was for a long time thought that the nature of the host galaxy determined the radio class with radio-quiet AGN in spiral hosts and radio-loud AGN in ellipticals. However, recent observations with the Hubble Space Telescope have shown that at high luminosity nearly all AGN lie in elliptical galaxies. It is now widely suspected that the angular momentum of the central black hole might be the determining factor, since the orbital motions of charged particles around the black hole might determine whether or not electromagnetic effects will be sufficiently powerful to generate and collimate jets.

Active Galaxy

A galaxy that has an exceptionally high luminosity and which radiates large amounts of non-stellar radiation. A typical active galaxy will exhibit all or most of the following properties: an overall luminosity in excess of 10^{37} watts; a much higher output of x-ray, ultraviolet, infrared and radio radiation than a normal galaxy; a highly luminous and compact central core, known as an active galactic nucleus (AGN), which, in many cases, varies rapidly in brightness; narrow jets of radiating matter emerging from the central core; large-scale clouds of radio-emitting material; and, in some cases, broad emission lines in its spectrum. Much of the energy radiated by an active galaxy is emitted by charged particles moving at high speeds in magnetic fields (synchrotron radiation) rather than by stars

Active galaxies are classified according to their appearance, luminosity and spectra into the following principal types: Seyfert galaxies, radio galaxies, quasars, BL Lacertae objects (BL Lacs) and blazars.

Active Optics

A system that enables the shape and relative positions of the principal optical elements of a telescope to be adjusted to compensate for optical errors induced by a variety of possible sources of deformation in the system. Sources of deformation include: flexure of the primary mirror or telescope structure as the orientation of the telescope changes, thermal effects induced by changing temperatures, buffeting by wind or manufacturing errors in the shape of the mirrors. An active optics system monitors the quality of the image of a reference star, calculates the optical errors (including, for example, coma and astigmatism) and adapts the shape and relative positions of primary and secondary mirrors to counteract these errors. The shape of the primary mirror is controlled by a system of actuators that applies forces to the rear of the mirror. The primary mirror in such a system has to be thin relative to its diameter in order to respond effectively to these forces. For example, the primary mirror in each of the four telescopes that comprise the European Southern Observatory's Very Large Telescope has a diameter of 8.2 m, a weight of 23 tonnes and a thickness of only 175 mm, the shape of each mirror being controlled by 150 actuators.

Active Region

A localized region of the Sun's surface and atmosphere that displays most or all of the following phenomena: sunspots, faculae, plages, filaments, prominences, flares and bright condensations in the corona. The underlying feature of a typical active region is a bipolar magnetic region, an area of concentrated magnetic fields that, although often complex in structure, contains approximately equal quantities of positive and negative magnetic flux. The overall diameter of an active region, within which the general magnetic field strength is about 0.01 T, may be several hundred thousand kilometers; localized fields of up to 0.4 T occur within sunspots.

An active region begins to form when magnetic flux tubes (bundles of magnetic field lines) erupt through the photosphere from below to create loop structures that have positive magnetic polarity where they emerge from the solar surface, and negative polarity where they re-enter the solar surface. Typically, an active region will grow to its maximum extent in about 10 days and may persist for several months, declining slowly as its underlying magnetic fields dissipate. The sunspots that form within an active region usually disappear within 2–4 weeks.

See also: chromosphere, corona, faculae, filament, flare, plage, prominence, sunspots.

Adams, John Couch (1819–92)

Born in Laneast, Cornwall, England, he became fellow and mathematical tutor at Cambridge. He developed a procedure for numerical integration of differential equations and, inspired by MARY SOMERVILLE, he deduced mathematically the existence and location of the planet Neptune from its perturbations on the planet Uranus. Neptune was discovered by JOHANN GALLE in Berlin, in September 1846, using URBAIN LEVERRIER's independently computed position. Adams' claim to priority was advanced shortly thereafter, and it transpired that, with a letter of introduction from JAMES CHALLIS in Cambridge, Adams had applied to GEORGE AIRY, the Astronomer Royal, for some kind of assistance, though he failed to secure an interview with Airy, and nothing further happened. This seems to have been because of Adams' youth and unforceful personality, and Airy's unapproachability. Challis himself made a start to a somewhat half-hearted search for Neptune on the basis of Adams' calculations, but was overtaken by Galle. Adams was appointed professor of astronomy at Cambridge in 1858, and was director of the Cambridge Observatory from 1861.

Adams, Walter Sydney (1876–1956)

Born in Antioch, Syria, to American missionary parents, he worked under GEORGE HALE at Yerkes Observatory at the University of Chicago, accompanying Hale to California to set up the Mount Wilson Observatory, and becoming its director on Hale's retirement. He helped design the 200 in telescope for Mount Palomar Observatory. His method of spectroscopic parallaxes, a technique using spectra to give indications of stellar luminosities, made it possible to measure the distances to more distant stars than those whose parallax could be measured by the trigonometric method.

Adaptive Optics

A system that enables the optical surfaces of telescope mirrors to be continuously modified to compensate for distortions in incoming light waves as they pass through the Earth's atmosphere. Light waves from a distant source, such as a star, arrive at the top of the atmosphere as straight parallel wavefronts (rather like waves advancing across the surface of the ocean) but are then distorted by the atmosphere and arrive as 'corrugated' wavefronts at the primary mirror of a telescope. Because all parts of such a wavefront cannot be focused at the same point, the image quality is degraded, so limiting, quite severely, the resolutions that can be achieved by large ground-based telescopes. The adaptive optics technique senses and counteracts these wavefront distortions.

Wavefront distortions are sensed by monitoring a suitable bright star, if there happens to be one in the field of view of the telescope, or by monitoring an artificial 'star' generated by shining a powerful sodium laser beam into the upper atmosphere. The laser beam stimulates the emission of light by sodium atoms in a layer that exists at an altitude of about 100 km, so generating a star-like point of light that may be positioned conveniently close to the object that is being studied by the telescope. Because light from this artificial 'star' travels down to the telescope along (almost) the same path as the light from the object of interest, it suffers the same wavefront distortions. A wavefront sensor measures the distortions, and a real-time control computer instructs a set of actuators located behind a thin flexible mirror to alter the mirror shape and thereby cancel out the wavefront distortions. Because the distortions induced by the atmosphere are continually changing, the system has to sense and respond to them as rapidly as possible—tens or even hundreds of times per second.

In principle, adaptive optics systems ought to be able to allow telescopes to achieve resolutions approaching their theoretical limits. A system of this kind has been in operation on the European Southern Observatory's 3.6 m New Technology Telescope since 1992. Adaptive optics systems on the Very Large Telescope (an array of four 8.2 m telescopes) are expected to enable this instrument to achieve its theoretical (diffraction limited) resolution at near-infrared wavelengths.

Adelard of Bath (1075–1160)

Born in Bath, England, a teacher and translator of scientific work from the Arabic, Adelard traveled in France, Italy, Syria and Palestine. On returning to Bath, he translated Euclid's *Elements* from Arabic, and his translation became for centuries the chief geometry textbook in the West. He also translated the *zij* (astronomical table) of Muhammed ibn Musa al-Khwarazmi. He wrote works on the abacus and on the astrolabe.

Aglaonike (*c*. 200 BC)

A natural philosopher of ancient Greece, she is referred to as a sorceress who could make the Moon disappear at will. She might therefore be regarded as the first recorded woman astronomer in that she seems to have mastered the art of predicting lunar eclipses, presumably by knowledge of the Metonic cycle, by which lunar eclipses repeat themselves every 19 years. The cycle was discovered in the fifth century BC by Babylonian astronomers and named for METOS.

Air Force Maui Optical Station

Located on the island of Maui, Hawaii. Instruments include visible and infrared sensors and the 3.67 m (145 in) Advanced Electro-Optical System (AEOS) telescope, which is fitted with adaptive optics. This is the US Air Force's largest and most advanced telescope system. The telescope is used to track and image Earth-orbiting satellites and astronomical objects such as asteroids.

The AEOS telescope was made available to the civilian astronomical community on 1 September 1999, under a pilot program agreed by the Air Force Office of Scientific Research and the National Science Foundation's Division of Astronomical Sciences. The agreement will make available 100 observing nights over a 2 year period to determine the level of interest in the AEOS facility from the US astronomical community.

Airglow

The airglow consists of the non-thermal radiation emitted by EARTH'S ATMOSPHERE. The thermal emission of Earth, heated by sunlight and subsequently radiating to space, takes place in the infrared portion of the spectrum, at wavelengths longer than 7 μm. In its simplest form, the airglow arises from de-excitation of molecules, atoms or ions excited by solar UV photons or energetic particles, and the resulting emitted photons are generally, although not exclusively, located in the visible and UV ranges of the spectrum. The existence of a night sky glow, long after sunset, shows that indirect mechanisms play an important role in producing airglow. In this case, the initial energy, brought by solar photons, is stored in the high atmosphere under the form of radicals or molecules able to recombine through exothermic reactions during the night and produce atoms or molecules in their excited states, with subsequent photonic emissions. The airglow does not include the radiation produced by lightning or meteor trains. Although the distinction is more difficult to establish, auroral phenomena, occurring at high latitudes and resulting from localized, intense precipitation of particles whose origins are outside the atmosphere, are not considered as being airglow. In contrast to AURORAS, and in spite of the fact that the general mechanism of emission (excitation–de-excitation) is of the same nature, the airglow occurs at any time and any latitude, in a much less sporadic way.

Historically, the existence of a terrestrial component of the light in the night sky was recognized in the years around 1900. Yntenna, who first established by photometric methods the existence of airglow, remarked on the large variability of this phenomenon from night to night and showed that the star light scattered by atmospheric molecules was insufficient to explain the night sky light. Spectroscopic techniques showed that the green line of atomic oxygen at 558 nm was present over the whole sky at all times and confirmed the existence of a 'permanent aurora'. Rayleigh (JOHN WILLIAM STRUTT) showed in the 1920s that the geographical pattern of the oxygen green line differed from that of the aurora, and that the N_2^+ bands seen in auroras were absent from the night sky. Rayleigh first expressed the brightness of the green line in terms of the number of atomic transitions per second in a column of unit cross-sectional area along the line of sight. He gave his name to the photometric unit universally used today for airglow studies: one rayleigh (or 1 R) represents an omnidirectional emission rate of 10^6 photons per square centimeter per second. The oxygen red lines at 630–636 nm were predicted and observed around 1930, as well as the D line of sodium.

Although ground-based spectrophotometric instruments provide a convenient way to monitor the spatial and temporal variations of the airglow, they are not appropriate for the retrieval of the emission vertical profiles. One possibility is to use rocket-borne zenith photometers flown through the airglow layers. Differentiation of the signal with respect to altitude allows the retrieval of the local volume emission rate as a function of altitude. Another way to proceed is to perform airglow measurements from an orbital platform in limb viewing geometry. This technique has several advantages. Because the signal is integrated along a tangential path, the intensity of the measured signal is greatly enhanced. It makes weak features, like the airglow continuum emission, easier to detect and characterize. Second, the tangential view allows the separation of the background galactic signal from the atmospheric glow because the galactic signal is directly provided by measurements performed at very high altitudes, where the atmospheric density is virtually zero.

The vertical profiles of several identified night airglow lines, as observed from the space shuttle STS-37 mission orbiting at 267 km altitude, are plotted in figure 1. The well known green line of oxygen at 557.7 nm, produced by the $O(^1S) \rightarrow O(^1D)$ transition, covers a relatively narrow altitude region and strongly peaks around 100 km altitude. Some emission is also recorded in the red line of oxygen at 630 nm, due to the $O(^1D) \rightarrow O(^3P)$ transition. The signal at 762 nm results from radiative de-excitation of an excited state of O_2. The case of atomic and molecular oxygen lines will be treated in a more detailed way in the following section. The D line of Na at 589 nm, due to $Na(^2P) \rightarrow Na(^2S)$, peaks around 90 km, similarly to the OH (6–0) Meinel band at 527 nm. The OH emission is produced by the reaction cycle

$$H + O_3 \rightarrow OH^* + O_2^*$$

where OH^* is a rotationally excited level of OH, with a vibrational quantum number ν less than 9 (no bands originating from $\nu > 9$ are detected) and a recycling mechanism of the type

$$OH + O \rightarrow H + O_2.$$

The 527 nm band is produced by the $\nu = 6 \rightarrow 0$ de-excitation of OH*. Note that the strong peak at low altitude in the 630 nm emission is due to the (9–3) band of OH. Because the chemistry of sodium also involves ozone (O_3) through the cycle

$$Na + O_3 \rightarrow NaO + O_2$$
$$NaO + O \rightarrow Na + O_2$$

a coupling between the airglow OH intensities and the Na density (derived either from lidar measurements or from airglow measurements) may be expected, and is definitely exhibited by measurements.

There is also a bright emission that extends from 400 to 600 nm. It is due to O_2 in the near ultraviolet and blue ranges, up to 480 nm, and NO_2 at longer wavelengths. The O_2 band emission mainly consists of Herzberg I, Herzberg II and Chamberlain bands, as detailed in the next section. The NO_2 diffuse feature may be attributed to the radiative recombination of NO and O, and is a true continuum.

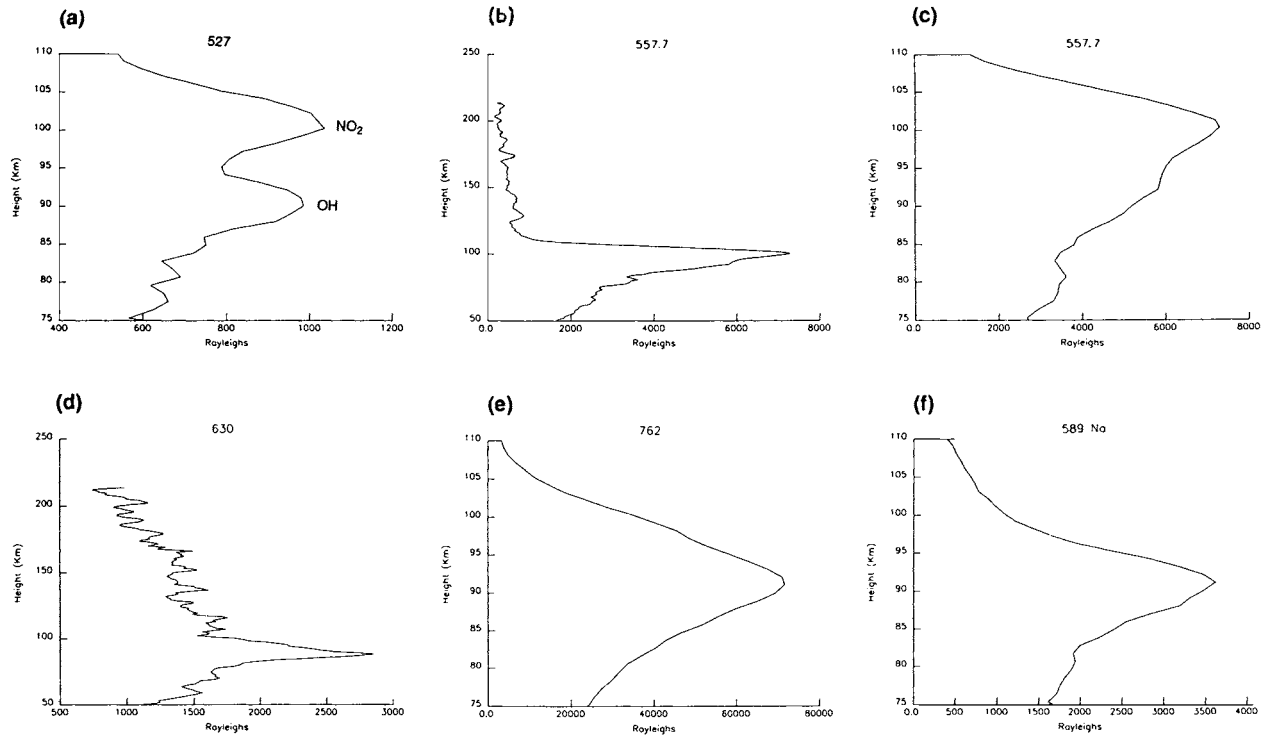

Figure 1. Altitude profiles of Earth's airglow in six wavelength ranges as seen from the space shuttle on the STS-37 mission. (From Mende *et al* 1993 *J. Geophys. Res.* **98** 19 117.)

A profile taken at 527 nm is shown in figure 1. The marked airglow peak between 95 and 105 km altitude is in good agreement with microwave measurements of thermospheric NO made during the same solar cycle, suggesting a maximum concentration region between 100 and 110 km.

The study of upper atmospheric airglow (dayglow and nightglow) emissions, either from ground-based spectrometry or by using spectrometers as well as imagers on board satellites like the Dynamics Explorer and Space Shuttle, has seen very substantial progress in the last 20 years. These measurements have allowed the characterization of thermospheric and ionospheric processes, in fields of both aeronomy and dynamics, with the help of laboratory and theoretical advances. The interpretation of airglow measurements is extremely complicated, involving the detailed characteristics of the excitation fluxes (solar UV/EUV, particles), interaction mechanisms (direct excitation of molecules, atoms or ions, indirect excitation through dissociation and ionization processes, as well as chemical reactions), chemical cycles, radiative transfer of airglow light. Oxygen emission lines in the nightglow are now detailed.

Excitation of oxygen emissions in the nightglow of Earth

The red doublet of oxygen at 630 nm and 636.4 nm, resulting from the $O(^1D) \rightarrow O(^3P)$ transition, that is from the first excited level to the ground state, with transition probabilities of 0.0069 and 0.0022 s^{-1} respectively, is observed during several hours after sunset. Since the average emission time of $O(^1D)$ is equal to the inverse of the transition probability, that is a few minutes, direct excitation of oxygen atoms by solar UV photons followed by de-excitation cannot explain the persistence of the red glow for a long time after sunset. The source of $O(^1D)$ during night time is dissociative recombination of O_2^+ ions

$$O_2^+ + e^- \rightarrow O + O(^1D).$$

The O_2^+ ions result from the night time decay of ionization which is controlled by charge exchange reactions that converts O^+ ions into O_2^+ ions.

The vertical distribution of the red line emission is complex and may be shown to evolve with time in a different way at different altitudes. Below 200 km, the red line emission is weak because O^* is deactivated (or 'quenched') by collisions with air molecules in a time smaller than the emission time. Above 200 km, the combined effects of the collisional quenching rate, which decreases with altitude, and the vertical variation of the electronic density, which increases with altitude, results in a strong increase, for increasing altitudes, of the red line glow. An important application of the measurement of thermospheric nightglow emissions, like the oxygen red line, is the inference of winds and temperatures from high-resolution spectroscopy. By using Fabry–Perot

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and Michelson interferometers, the thermospheric neutral wind at the 250 km altitude level has been retrieved from the O(^{1}D) 630 nm emission line by measuring the associated Doppler shift, which yields the line-of-sight wind vector. Neutral temperatures may be inferred from the width of the line. Doppler spectroscopy of airglow lines is a powerful means to study the dynamics of the thermosphere, strongly controlled by thermal tides and general wave activity.

The green line of oxygen at 558 nm, which results from the O(^{1}S)→O(^{1}D) transition between the second and the first excited states, is known to arise from the 100 km neighborhood, that is definitely lower atmospheric levels than the red lines. Although a part of the green line may arise from dissociative recombination of O_2^+ in the F region

$$O_2^+ + e^- \rightarrow O^* + O^*$$

another mechanism must be invoked to explain the low emission altitude of this line. Sydney Chapman proposed a mechanism of 'photochemical excitation'

$$O + O + O \rightarrow O_2 + O(^1S)$$

where one of the O atoms is excited by some of the energy liberated in the association of two O atoms. This process results in a maximum O concentration around 100 km, which is consistent with the location of the green line emission. De-excitation of O(^{1}S) into O(^{1}D) occurs through quenching by ambient air molecules (mainly molecular nitrogen).

The so-called Chapman process, although it may participate in the green line emission, is now thought to be of secondary importance. At the beginning of the 1960s, Barth and Hildebrandt found in the laboratory that the emission produced by the previous process is much too small to account for the observed glow. This result stimulated Barth to put forward, in 1964, the following two-step mechanism:

$$O + O + M \rightarrow O_2^* + M$$

where M is an air molecule and O_2^* an excited state of the O_2 molecule, followed by the excitation transfer process

$$O_2^* + O(^3P) \rightarrow O_2 + O(^1S).$$

The net effect of these two reactions, obtained by adding them, is similar to the effect of the single Chapman reaction. The other loss processes are deactivation through quenching by collision with an air molecule

$$O_2^* + M \rightarrow O_2 + M$$

or radiation of a photon through radiative de-excitation

$$O_2^* \rightarrow O_2 + h\nu.$$

Therefore, the Barth process may give rise simultaneously to both O(^{1}S) (green line) and O_2 (762 nm line) emissions. Comparison of the two corresponding profiles in figure 1 may be shown to be consistent with the two-step scheme, despite the 10 km difference between the peak altitudes.

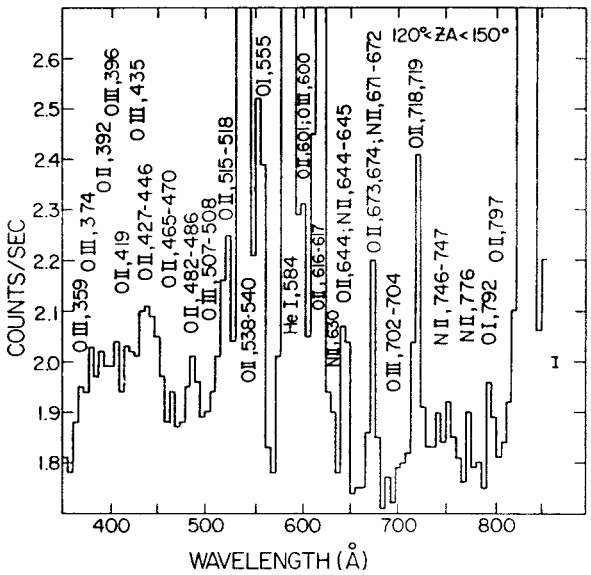

Figure 2. Nadir viewed UV dayglow spectrum between 350 and 950 Å acquired by the STP78-1 satellite from 600 km between 50°N and 50°S latitudes. (From Chakrabarti *et al* 1983 *J. Geophys. Res.* **88** 4898.)

Dayglow and twilight emissions

Airglow emissions are also observed during the day, and they mainly reflect the diurnal variation of the concentration of emitting species. Twilight spectra may be observed at the transition between the dark and fully illuminated atmosphere, as the shadow height moves vertically over the full range of emissive layers. In the day time, several lines and bands are very bright, mainly due to higher production rates. Indeed, dayglow and twilight emissions mainly result from direct excitation by solar ultraviolet photons, photoelectrons produced through ionization processes in the ionosphere, and by resonance scattering or fluorescence of solar radiation. Such energetic phenomena result in a complex ultraviolet dayglow spectrum, as shown in figure 2. These measurements were made from an Earth-orbiting satellite (STP78-1), since ultraviolet photons are prevented from penetrating down to the ground due to the screening effect of the atmosphere. Even at near-UV or visible wavelengths, dayglow are difficult to acquire with ground-based instruments because of the high level of the background scattered solar light.

The short-wavelength ultraviolet spectrum is dominated by singly ionized and neutral lines of oxygen (O I, O II) and nitrogen (N I, N II). These lines are produced by ultraviolet photons and photoelectron impact. Short-wavelength lines are produced by de-excitation from high-energy upper states, which cannot be excited by chemical or recombination reactions. Several atomic and ionic lines in the dayglow spectrum are also lines that appear in the solar spectrum, like the He I line at 584 Å. In the case of helium, this phenomenon is due to resonant scattering of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the He solar emission line. Similar features are observed at 834 Å (O II triplet), 1216 Å and 1025 Å (H I, Lyα and Lyβ), 1302–1306 Å (O I triplet) and others wavelengths. They are due to resonant scattering or fluorescence.

Molecular oxygen emissions in the airglows of Earth, Venus and Mars

Whereas the case of the O(^{1}S) state is well understood, the detailed process of O_2 emissions is still not well known. In addition to the discrete 762 nm O_2 band, there is a near-UV–blue extended emission attributed to Herzberg and Chamberlain bands. In previous reactions, the excited bound state O_2^* of O_2 can be $A\,^3\Sigma_u^+$, $A'\,^3\Delta_u$ or $c\,^1\Sigma_u^-$ (figure 3). The main precursor of O(^{1}S) could be $O_2(c\,^1\Sigma_u^-)$, but it is still not certain what the nature of the precursor is, and that is still an active field of investigation today. In Earth's atmosphere, the Herzberg I system is the major cause of the blue nightglow continuum, with an average emission of 400 R. From spaceborne observations of the Venus airglow by the Soviet Venera probes, similar oxygen airglows were found, although in quite different amounts. The Venus molecular oxygen nightglow shows a strong pre-eminence of the Herzberg II system (2700 R). Such large differences are due to the different chemical compositions of the atmospheric environment for Earth and Venus (see VENUS: ATMOSPHERE). In the luminous layers, the ambient air (N_2+O_2 for Earth, CO_2 for Venus) density is nearly 100 times larger on Venus than on Earth, the reverse situation occurring for O (three times less on Venus than on Earth). Because the collisional quenching of $O_2(A\,^3\Sigma_u^+)$ is mainly realized by air molecules, whereas $O_2(c\,^1\Sigma_u^-)$ is preferentially quenched by collisions with O, Herzberg I bands are weak on Venus and Herzberg II bands are strongly enhanced with respect to the case of Earth (2700 R on Venus versus 100 R on Earth). Another interesting feature is the extreme weakness of the oxygen green line in Venus nightglow (5 R versus 120 R on Earth), which was an important element in favoring the Barth mechanism over to the Chapman process.

As seen in figure 3, a glow of the infrared atmospheric system of $a\,^1\Delta_g \rightarrow X\,^3\Sigma_g^-$ is expected in the infrared, at 1.27 μm. This glow, first detected on Venus by the French spectroscopist Pierre Connes and his collaborators at the end of the 1970s is quite intense (>1 MR, that is 10^6 R). Such a strong emission is also measured on Earth. Due to the long radiative lifetime of $O_2(a\,^1\Delta_g)$ (1 h), the analysis is complicated by transport across the terminator. Photolysis of O_3 under sunlit conditions according to the following reaction

$$O_3 + h\nu \rightarrow O_2(a\,^1\Delta_g) + O(^1D)$$

constitutes part of the source in the dayglows of Earth and Mars, but it is negligible on Venus. The major source in the nightglows of all the terrestrial planets, the dayglow of Venus and a part of the dayglows of Earth and Mars, is the recombination of O atoms produced in the photolysis of O_2 on Earth and CO_2 on Venus and Mars (see MARS: ATMOSPHERE).

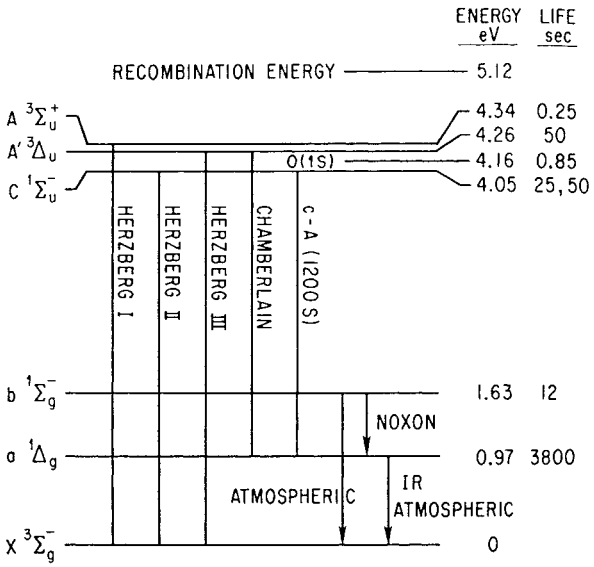

Figure 3. The six lowest levels of molecular oxygen and the corresponding band systems (from Krasnopolsky 1983).

Connes measured individual rotational lines of this band in the Martian spectrum with the 5 m telescope on Mount Palomar in 1973 and 1975. Rotational temperatures and airglow intensities were derived from the spectra. In each spectrum, equivalent widths of about 30 lines were measured to be typically 0.005–0.01 nm. By ratioing the equivalent width to the line strength, and by examining the dependence of this ratio on the energy of the upper rotational state of the transition, a rotational temperature of 200 K was deduced, which corresponds to the real temperature averaged over the airglow altitude profile. Typical airglow intensities of 3 to 30 MR, depending on latitude, were found. Assuming the quenching rate coefficient by air molecules (CO_2 on Mars) is known, it is possible to infer the ozone amount from 1.27 μm airglow measurements, although in a rather inaccurate way.

Airy Disk

The bright spot at the center of the diffraction pattern that is formed when a point source, such as a star, is imaged at the focus of a telescope. Light waves from a distant star arrive at the Earth as a series of parallel wavefronts (rather like waves rolling onto a beach). When these wavefronts are interrupted at the edge of a telescope's aperture (the rim of the objective or primary mirror), and are brought to a focus, interference effects between different parts of each wavefront result in the formation of a diffraction pattern. For a point source, the resulting image (assuming a perfect optical system) consists of a central spot of light surrounded by a series of light and dark fringes, or rings. According to theory, 84% of the light energy is concentrated into the central spot (the Airy disk), the diameter of which depends on the aperture of the telescope and the wavelength of the light. The radius of the first dark minimum in light intensity, that lies immediately outside the Airy disk, is given, in radians, by $1.22\lambda/D$, where λ denotes wavelength and D the aperture of the telescope. The central spot is known as the Airy disk because this type of diffraction pattern was first investigated by Sir George Biddell Airy (1801–92), the seventh Astronomer Royal.

Airy, Sir George Biddell (1801–92)

A brilliant Cambridge mathematician (Senior Wrangler 1823, i.e. leader of the graduating mathematics class), Airy became the seventh Astronomer Royal in 1835 after a brief period as Lucasian Professor at Cambridge. His output was prodigious, and he published nearly 400 scientific papers and 150 reports on various scientific issues, such as the gauge of railways, spectacles to correct astigmatism, and methods to correct for compass readings in ships made of iron. His work on optics is recognized by the use of the term *Airy disc* for the resolution element of a telescope due to diffraction at its aperture, which he studied. As Astronomer Royal, he saw that the Royal Observatory at Greenwich was re-equipped with modern instruments and that its work was carried out punctiliously by its many human 'calculators' and observers, insisting that everything was carried out in the best way, namely his way. This regime was effective in raising standards. He himself determined the density of the Earth, the mass of the planet Jupiter and its rotation period. He calculated the orbits of comets and cataloged stars. He made numerous contributions to the prediction of the motion of the Moon, and analysed transits of the planet Venus and eclipses, including the eclipse predicted by THALES. As a result of the accuracy of the observations made under Airy at Greenwich, and his practical exploitation of the railway telegraph to distribute it, Greenwich Mean Time was established in 1880 as the official time service throughout Britain, and afterwards became the basis for the timekeeping of the world.

Aitken, Robert Grant (1864–1951)

Astronomer, born in California, Aitken became director of the Lick Observatory. He made systematic visual surveys of binary stars, measuring their positions visually. His massive *New General Catalogue of Double Stars* (1932) contained data on 17 000 stars that allowed orbit determinations of many, from which it was possible to calculate data on the masses of the stars' components. He also measured positions of comets and planetary satellites and computed orbits.

al-Battani, Abu Abdullah [known as Albategnius] (*c*. 868–*c*. 929)

Born in Harran, in present-day Syria, al-Battani spent most of his life in Raqqa, situated on the bank of the Euphrates, where he was educated and flourished as a scholar and a Sabean which means 'worshipper of the stars'. His best-known achievement was the determination of the solar year as being 365 days, 5 hours, 46 minutes and 24 seconds, an extremely accurate value that was used in the Gregorian Calendar reform of the Julian Calendar. Using trigonometrical rather than geometrical methods, he also determined the true and mean orbit of the Sun, proving the variation of the apparent angular diameter of the Sun (an indication of the variable distance between Sun and Earth) and the possibility of annular eclipses. He wrote a number of books on astronomy and trigonometry, his most famous book being his astronomical treatise with tables (a *zij*), which was translated into Latin in the twelfth century as *De Scienta Stellarum—De Numeris Stellarum et Motibus*. His treatise on astronomy was extremely influential in Europe till the Renaissance, with translations available for centuries in several languages.

Albedo

A measure of the reflectivity of a material or object. For bodies in the solar system, albedo is the proportion of sunlight falling on them that is reflected away. It is measured on a scale from 0 (a perfectly absorbing black surface) to 1 (a perfectly reflecting white surface).

Albedo may be defined in various ways. The most common is *geometrical albedo*, sometimes called *physical albedo*. This is the ratio of the amount of light reflected from an object, as viewed from the direction of the Sun, to the amount that would be reflected by a perfectly diffusely reflecting sphere (which by definition has an albedo of 1) of the same size and at the same distance as the object. As well as applying to visible light, geometrical albedo may be defined for radiation in any specified wavelength range; *bolometric geometrical albedo* applies to all wavelengths. *Bond albedo*, also known as *spherical albedo*, is defined similarly but for radiation of all wavelengths reflected in all directions; it is named after George Phillips Bond. Another measure is *hemispherical albedo*: the ratio of scattered to incident light as a function of the angle of incidence, and again the body is assumed to be a perfectly diffusely reflecting sphere.

Of the major planets, Mercury has the lowest geometrical albedo, at 0.11 (comparable to the Moon's 0.12), while Venus, by virtue of its blanket of highly reflective clouds, has the highest, 0.65. The lowest albedo in the solar system seems to be possessed by the particles that make up the rings of Neptune, which probably have a value close to the theoretical lower limit of zero. Asteroids which originally formed between about 2.5 and 3.5 AU from the Sun, where it was cool enough for dark carbonaceous compounds to condense from the solar nebula, but not water ice, have albedo values as low as 0.02. The highest measured albedo is that of Saturn's satellite Enceladus, to which some sources assign a value of 1.0.

Albireo

The star β Cygni, said to represent the eye of the swan in the ancient constellation figure. It is seen as a single star of apparent magnitude about 2.9 with the unaided eye, but with good binoculars or a small telescope it appears as a beautiful double, comprising an orange star (β^1 Cyg) of apparent magnitude 3.05, spectral type K3II, with a bluish-white companion (β^2 Cyg) of apparent magnitude 5.17 and spectral type B8V. Their separation is 34.4″ at position angle 54°. The system is 380 light-years distant, having a parallax of 0.008″. The absolute magnitudes of the two stars are β^1 Cyg −2.3, β^2 Cyg −0.2.

With more powerful instruments β^1 Cyg can be further resolved: it is a binary system with components of apparent magnitude 3.4 and 5.5, separated by 0.39″ at position angle 152°.

al-Biruni, Abu Raihan (973–1048)

Born in Kheva near Ural, present-day Uzbekhistan, al-Biruni was a polymath and traveler (to India), making contributions in mathematics, geography and geology, natural history, calendars and astronomy. His book *Qanun-i Masoodi*, which he dedicated to his patron Sultan Masood, discusses astronomy, trigonometry, solar, lunar and planetary motions, including the question whether the Earth rotates or not. He undertook experiments (observations) related to astronomical phenomena, for example eclipses and the dates of the equinoxes, and determined that, compared with the speed of sound, the speed of light is immense. He recognized the Milky Way as 'a collection of countless fragments of the nature of nebulous stars'. Al-Biruni's quest for scientific knowledge is epitomized by his statement that the phrase *Allah is omniscient* does not justify ignorance.

Aldebaran

The star α Tauri, a red giant of spectral type K5III, apparent magnitude 0.87. Its distance is 65 light-years, its parallax 0.050″. The absolute magnitude is −0.6. Aldebaran appears at the eastward corner of the striking triangular open cluster the Hyades, although it is not actually a member of the cluster which is much more distant (about 100 light-years). The name derives from the Arabic *Al Dabaran*, 'the Follower'—presumably of the Pleiades.

Aldebaran was one of the 'Royal Stars' or 'Guardians of the Sky' of the Persian astronomer/astrologers *c*. 3000 BC. Although not the brightest stars these four were carefully chosen, apparently to mark the seasons, as they are approximately 6 h apart in right ascension. Aldebaran (ancient Persian name Tascheter) was prominent in the evening sky in March and was associated with the vernal equinox; the others were Regulus (summer solstice), Antares (autumnal equinox) and Fomalhaut (winter solstice).

al-Farghani, Abu'l-Abbas Ahmad ibn Muhammad ibn Kathir (*c*. 860)

Born in Farghana, Transoxiana (northern Iran), he wrote *A Book on Celestial Motion and Science of the Stars* (*Kitab fi al-Harakat al-Samawiya wa Jawami Ilm al-Nujum*), which was translated several times into Latin and Hebrew starting in the twelfth century. The book spread knowledge of Ptolemaic astronomy in Europe, at least until this role was taken over by Sacrobosco's *Sphere* on which it was based; DANTE, for example, used it as a source of astronomical knowledge. He determined the diameter of the Earth to be 6 500 miles and. found the distances and diameters of the planets. He also wrote a summary of the *Almagest* and a *Book on the Construction of Sun-dials*. He was additionally an engineer, but not a very good one, judging by the story that he built the beginning of an irrigation canal from the Tigris deeper than the rest of its length, so that not enough water would run through to its other end. The explanation given for Al-Farghani's mistake is that, a theoretician rather than a practical engineer, he had never successfully made anything.

Alfonso X [Alfonso X of Castile; Alfonso the Astronomer; Alfonso the Wise] (1221–84)

King of León and Castile (from 1252), born in Burgos, Spain, founded the Castilian national culture. He commissioned the first general history of Spain to be composed in Castilian, a translation of the Old Testament, a great code of laws (*Siete Partidas*) and a planetary table. The planetary tables were a development of the work of Azarchiel (the *Toledan Tables*). These included data on astronomical phenomena, and calculations of the future positions of the planets according to Azarchiel's re-working of the Ptolemaic theory. It was Alfonso who financed and directed a team of astronomers led by Ishak ben Said, called Hasan, and Jehuda ben Mose Cohen to make the calculations, which were finished just as Alfonso became king, and published as the *Alfonsine Tables*. They survived as the standard work of astronomical prediction in Europe in manuscript and printed form for 300 years. Alfonso remarked during this time, apparently because of the arbitrariness and complexity of the Ptolomaic theory of the planets, that he wished that he had been around at the time of the creation since he could have given the Almighty some good advice. The major discrepancies which built up with time between the calculations in the *Alfonsine Tables* and reality was the inspiration to TYCHO BRAHE in 1563 at the age of 16 to begin making systematic astronomical observations, a motivation stimulated into action by his startling observations of the New Star of 1572.

Alfvén, Hannes Olof Gösta (1908–95)

Physicist, born in Norrkorping, Sweden, Nobel prizewinner (1970), developed plasma physics, and applied theory to a wide range of physical and astrophysical phenomena including charged particle beams in accelerators, and interplanetary and magnetospheric physics. He founded magnetohydrodynamics, the branch of physics which shows how magnetic and electrical phenomena act on gases that are hot and in motion. His theory is used in rocket propulsion, aerodynamic braking of space vehicles, explanations of solar–terrestrial 'weather', the formation of comet tails, the formation of the solar system, the dynamics of plasmas in our Galaxy, and the fundamental nature of the universe itself. In 1937 he postulated the galactic magnetic field as the 'bottle' which contained cosmic rays, and in 1950 identified non-thermal radiation from astronomical sources as synchrotron radiation, which is produced by fast-moving electrons in the presence of magnetic fields: this is essentially the theoretical basis for most of radioastronomy. Alfvén held positions in Uppsala, Stockholm and California. His ideas were often original and therefore regarded as unorthodox: his career was marked by disputes over publications and controversy with established leaders. He was active in the worldwide nuclear disarmament movement. *Alfvén waves*, named after him, are electromagnetic waves that propagate through a highly conducting medium, such as the ionized gas of the Sun.

Algol

Algol, also known as β Persei, is the prototype of a class of ECLIPSING BINARY STARS that undergo dramatic brightness changes during the eclipses. Like other Algols, Algol itself consists of a hot, unevolved primary and a cool, evolved secondary. It is this large difference in temperatures between the two stars that gives rise to the dramatic eclipses. When the hot primary is eclipsed by the cool secondary, the overall brightness of the system drops from its out-of-eclipse brightness of 2.1 magnitudes to about 3.4 magnitudes. These eclipses, repeating every 2.87 days, are easily seen with the naked eye, and it is obvious that the ancients observed them given that Algol is invariably associated with something evil or demonic. The name Algol comes from the Arabic *Ra's Al Ghul* meaning 'the head of the demon.' The Greeks saw Algol as the blinking eye of Medusa, whose severed head was held aloft by the hero Perseus. The modern discovery of the eclipses was made by MONTANARI in 1670 and their proper explanation was made by GOODRICKE in 1782.

A triple system

Algol has been studied extensively from the radio to the x-ray end of the spectrum with techniques ranging from photometry and spectroscopy to interferometry. Algol is actually a triple system, with the eclipsing pair known as AB and the tertiary component Algol C orbiting them with a period of 1.86 years. Algol A, the hot primary, is a B8 V star and Algol B is a K subgiant, while Algol C is a late A or early F star.

Close binary evolution

Algol has played an important role in our understanding of the evolution of CLOSE BINARY STAR systems. The Algol Paradox arose when researchers discovered that the less massive secondary was more evolved than the primary. Since high-mass stars evolve more rapidly than low-mass stars, Algol presented a puzzling situation. Through the work of Hoyle, Morton and others, the paradox was resolved when they showed that the now less massive secondary had once been the more massive one. When it evolved to core hydrogen exhaustion and expanded, it reached the inner critical surface, also known as the ROCHE LOBE. Having the more massive component of a binary in contact with the Roche lobe leads to an instability that results in rapid mass transfer to the other component. The mass transfer is so extensive that it reverses the ratio of the masses, leaving the system in a semi-detached configuration (one star filling its Roche lobe while the other is smaller than the lobe).

Evolutionary studies by Sarna indicate that the system initially consisted of $2.8M_\odot$ and $2.5M_\odot$ stars. The $2.8M_\odot$ star evolved, reached its Roche lobe, transferred mass to the other star and now has a mass of $0.8M_\odot$. The initially $2.5M_\odot$ star now has a mass of $3.7M_\odot$, meaning that $0.8M_\odot$ was lost from the system.

Current work

Current work on Algol is focused primarily on studying the nature of the circumstellar matter and its interaction with the two stars. Doppler tomography and polarimetry show promise as tools to uncover the nature of the circumstellar matter.

Algonquin Radio Observatory

A Canadian radioastronomy observatory in Ontario. The main instrument is a 46 m (150 ft) fully steerable dish which began operation in May 1966. The telescope was operated by the National Research Council of Canada until 1989. It is now jointly supported by the Space Geodynamics Laboratory of the Center for Research in Earth and Space Technology at York University in Toronto, and the Federal Government's Geodetic Survey Division in Ottawa.

Today it is mainly used in international VLBI programs to maintain the International Celestial Reference Frame. By measuring the precise celestial locations of about 100 quasars, geophysicists are able to study tectonic movements on the Earth, and measure variables such as the planet's rates of precession, nutation and rotation.

It is still used occasionally for astrophysical research. Recent examples include imaging of supernova remnants and precise determination of pulsar rotation.

al-Khwarizmi [al-Khawarizmi; al'Khwarizmi], Abu Abd-Allah [Abdullah; Ja'far] Mohammad [Muhammad] ibn Musa [Bin Musa] (*c*. 800–*c*. 850)

Born at Khawarizm (Kheva), south of the Aral Sea, he flourished in Baghdad from 813 to 833. He was an astronomer and geographer but is best known as a mathematician. The word *algebra* was derived from his book *Al-Jabr wa-al-Muqabilah*. He brought into mathematics the use of zero and the rest of the Indian system of numerals (now known as 'Arabic numerals'), and developed the decimal system. His name survives in English in the word *algorithm*. The development of astronomical tables by him was a significant contribution to the science of astronomy, on which he also wrote a book derived from an earlier Sanskrit astronomical work, brought to Baghdad around AD 770. The contribution of al-Khwarizmi to geography is also outstanding, in that not only did he revise PTOLEMY's views on geography, but also corrected them in detail as well as his map of the world. His other contributions include original work related to clocks, sundials and astrolabes. His books were widely translated, and a twelfth century Latin translation of *Al Jabr* introduced this new science to the West.

Allegheny Observatory

At the Alleghany Observatory, University of Pittsburgh, the Thaw 0.76 m $f/18$ red-light refractor and Multichannel Astrometric Photometer is a major contributor of accurate parallaxes, stellar masses and the astrometic search for extra solar planets. Founded in 1869, the Observatory established the standard time service, often called Rail-Road Time.

Previous directors of note include Samuel Pierpont Langley, who began his experiments with the wing and invented the bolometer here; James Keeler, who showed the rings of Saturn to be made up of particles; John Brashear, known for his exceptional astronomical optics; and Frank Schlesinger the father of photographic astrometry.

Allende Meteorite

The largest known fall of a carbonaceous chondrite. On 8 February 1969 an exceptionally brilliant fireball was seen in the skies of northern Mexico, followed by a series of sonic booms. The next day a meteorite was found in the village of Pueblito de Allende. This was the first of hundreds of fragments, totalling 2 tonnes, subsequently collected from the surrounding area. The elliptical strewnfield—the name given to the area in which the fragments of a meteorite fall—measured about 7 × 50 km; the largest single fragment (110 g) was found at its far tip. It has been estimated that the parent body weighed as much as 30 tonnes.

Alpha Centauri

The star α Centauri, also known (especially to navigators) as 'Rigel Kentaurus' or 'Rigil Kent'. With an apparent visual magnitude of -0.28 it is the third brightest star in the sky. A telescope, however, shows it to be a binary system, the components being a yellow G2V star, α Cen A, of magnitude -0.01, and an orange K1V star, α Cen B, of magnitude 1.35. Their separation is currently 19.1″ at position angle 215°; the period is 81.2 years. The absolute magnitudes of the component stars are 4.3 for α Cen A and 5.7 for α Cen B. There is also a much more distant third member of the multiple star system, Proxima Centauri, of apparent magnitude 11.01; it is separated from the main pair by 2.2° at position angle 213°. Proxima (α Cen C) is so named as it is believed to be the closest star to the Sun, at a distance of 4.22 light-years, parallax 0.772″. The parallax of the main binary pair is 0.742″, equivalent to a distance of 4.39 light-years. Proxima is a red dwarf of very low luminosity (absolute magnitude 15.4, spectral type M5Ve). It is a noted flare star, which often (but unpredictably) brightens briefly by about one magnitude.

Alpha Centauri A+B

Alpha Centauri A and Alpha Centauri B comprise the closest BINARY SYSTEM to Earth. A third star, PROXIMA CENTAURI, is thought to be in orbit about the center of mass of Alpha Centauri A and B. Other common names for this binary include Rigel Kentaurus and Toliman.

The word Centauri translates to the centaur, a mythological creature that was half human and half horse. It is believed that this constellation was named for Chiron, an unusually wise and gentle creature who was a tutor to Heracles. When Heracles accidentally wounded the immortal Chiron with a poisoned arrow, Zeus graciously allowed him to die, giving him a place among the stars.

Alpha Centauri A and B are located in the southern sky at right ascension 14 hours 39 minutes 36 seconds and declination -60°, 50 minutes and 07 seconds at a distance of 4.4 light-years. Alpha Centauri A, with spectral type G2, has apparent and absolute magnitudes of 0.0 and 4.4 respectively. Alpha Centauri B, spectral type K1, has apparent and absolute magnitudes of 1.3 and 5.7 respectively. Note that the difference between absolute and apparent magnitudes for each star is the same. This is a direct result of the fact that they are at the same distance.

The supposed third star in the system, Proxima Centauri, is much dimmer. It has a spectral type of M5 and apparent and absolute magnitudes of 11.1 and 15.5 respectively. This star is believed to be orbiting about the center of mass for Alpha Centauri A and B along a hyperbolic orbit. It has been suggested that this star system could be extended to include as many as 12 stars.

Since this binary system is the closest to Earth, and may have additional members of non-trivial influence, it provides an excellent environment for studying gravitationally bound stellar systems that orbit about a common center of mass. Accurate measurements of the size, mass and orbital parameters for these stars are necessary in order to fine-tune methods for determining the same parameters for more distant multiple stellar systems.

Alpha Particle

Term that is sometimes used to describe a helium nucleus, a positively charged particle that consists of two protons and two neutrons, bound together. Alpha particles, which were discovered by Ernest Rutherford (1871–1937) in 1898, are emitted by atomic nuclei that are undergoing alpha radioactivity. During this process, an unstable heavy nucleus spontaneously emits an alpha particle and transmutes (changes) into a nucleus of a different (lighter) element. Studies of the way in which alpha particles were scattered by atoms in thin sheets of mica and gold led Rutherford, in 1910, to the discovery of the atomic nucleus.

Alpha particles are found in the solar wind and are produced in collision events in high-energy particle accelerators. An important nuclear reaction, called the triple-alpha reaction, which welds helium nuclei (alpha particles) together to form carbon nuclei, occurs in red giant stars.

Alpher, Ralph Asher (1921–)

Physicist, born in Washington, DC. With HANS BETHE and GEORGE GAMOW, he proposed in 1948 the 'alpha-beta-gamma' theory of the creation of the elements by successive addition of nucleons to hydrogen to build up the periodic table (the *alpha* part of the name of the theory referred to Alpher). This idea, subsequently shown by MARGARET BURBIDGE, Geoffery Burbidge, WILLIAM FOWLER and FRED HOYLE to be incorrect, became part of the 'big bang' model of the universe.

al-Sufi, Abu al-Rahman (903–86)

Persian astronomer, published works on astronomical instruments. Revised PTOLEMY's star catalog as the *Book of the Constellations of the Fixed Stars*, with improved magnitudes, stars named by reference to constellation figures (much copied, for example by ALFONSO X as *Libros del Saber de Astronomìa*), and nebulae, including the Andromeda Galaxy (M31). However, the work was not entirely original since not all the star positions were re-observed. Al-Sufi also mentions a 'nebulous star' north of delta Velorum, which is probably the open cluster IC 2391, and an asterism in Vulpecula (Brocchi's Cluster, Collinder 399, also known as the Coat-hanger Cluster).

Altazimuth Mounting

A telescope mounting that has axes in the horizontal and vertical planes to enable the telescope to be swivelled in altitude (perpendicular to the horizon) and azimuth (parallel to the horizon). This type of mounting is simpler, cheaper to construct, and less prone to flexure and changes of balance than the equatorial mounting. However, because (except for observers located at the north and south poles of the Earth) both the altitude and the azimuth of a celestial object change continuously as a result of its diurnal motion across the sky, the telescope must be driven around both axes at varying speeds. Because of the difficulties involved in achieving this before the development of computer control techniques, until recently the overwhelming majority of optical astronomical telescopes (apart from some small instruments and specialist amateur telescopes such as the Dobsonian) were attached to equatorial mountings. In recent years, altazimuth mountings in which the drive rates for the two axes are computer controlled have become the only way to construct large modern optical telescopes such as the two 10 m Keck telescopes (the largest individual optical telescopes), the component telescopes of the Very Large Telescope (VLT) and the 8 m Gemini instruments and are economical for all optical telescopes over, say, 2 m aperture. Altazimuth mountings are also widely used for large radio dishes.

Altitude

The angle between the horizon and a star, measured in a direction perpendicular to the plane of the horizon. Together with a value of azimuth, this specifies the position in the sky of a celestial body at a particular instant, as seen by an observer at a particular point on the Earth's surface.

Due to the rotation of the Earth, the altitude of a star continually changes. For example, an observer in the northern hemisphere will see a star rise in the east, reach its maximum altitude when due south (culmination), and set in the west. Observers located at the north or south poles, however, will see stars move parallel to the horizon, so maintaining constant altitude.

Altitude also refers to the height of an object (e.g. an artificial satellite) above mean sea level.

See also: azimuth.

Alvarez, Luis Walter (1911–88)

Physicist and astronomer, born in San Francisco, CA, professor at the University of California, Nobel prizewinner (1968) for his discoveries in particle physics. Used cosmic rays to 'x-ray' the pyramids of Egypt, finding in particular that the tombs in the Great Pyramid at Giza had no hidden rooms. Alvarez (and his son) discovered globally distributed iridium at the Cretaceous/Tertiary boundary in the Earth's geological record (which, described in terms of geological strata, is a widespread discontinuity in rock types and directions, and can be interpreted as a wholesale change in the Earth's climate). He proposed that the change of climate and the disappearance of the dinosaurs at that time, some 65 million years ago, resulted from a cataclysmic collision of an asteroid with the Earth, asteroids being relatively rich in iridium. The crater of the collision has since been identified in the Yucatan peninsula of north-eastern Mexico.

AM Herculis

AM Herculis (AM Her) is the prototype and brightest of a class of short-period CATACLYSMIC BINARIES (CB) in which a strongly magnetic WHITE DWARF accretes gas from a Roche-lobe filling sub-solar mass companion. The magnetic field is sufficiently strong ($B_1 \gtrsim 20$ MG; MG $= 10^6$ gauss) to affect qualitatively the most fundamental characteristics of the binary: preventing the formation of an accretion disk and forcing mass transfer to occur entirely through one or more gas streams; channeling flow near the white dwarf into a near-radial funnel which liberates its accretion energy in a shock above the magnetic pole; and synchronizing the rotation of the white dwarf to the orbital motion of the companion, such that all basic phenomena are orchestrated on a common period $P_{\rm spin} = P_{\rm orb}$.

Because the gas arrives at the white dwarf surface under virtual free-fall, the post-shock plasma temperature is high and AM Her-type binaries are strong x-ray emitters. Most of the current catalog of ∼50 such systems (see X-RAY BINARY STARS) results from all-sky satellite surveys for x-rays. AM Her itself was cataloged as a VARIABLE STAR a half-century before its identification with the x-ray source 3U 1809+50 attracted the attention of observers. With typical periods in the range $1.5 \lesssim P_{\rm orb} \lesssim 4$ h and stellar masses $M_1 \sim 0.6 M_\odot$, $M_2 \sim 0.2 M_\odot$, an entire AM Her-type binary would commonly fit within the disk of the Sun. The systems (figure 1) are therefore compact laboratories for studying the physics of high-temperature, magnetized PLASMAS as well as the magnetic interactions between stars.

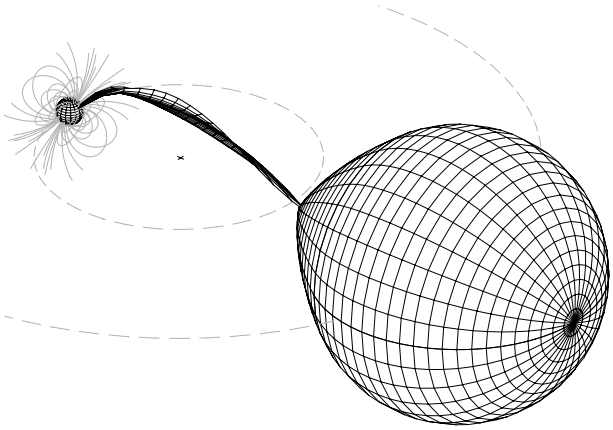

Figure 1. Sketch of the cataclysmic binary AM Her as seen from the Earth for a binary phase $\varphi \sim 0.1$. Gas flows through the inner Lagrangian point of the low-mass companion star in a largely free-falling stream onto an accretion shock located near the magnetic pole of the white dwarf. From here, the emission of x-rays and circularly polarized optical/infrared cyclotron emission dominates the light output of the system. The binary orbits in a counter-clockwise fashion around the center of mass (cross) in this figure.

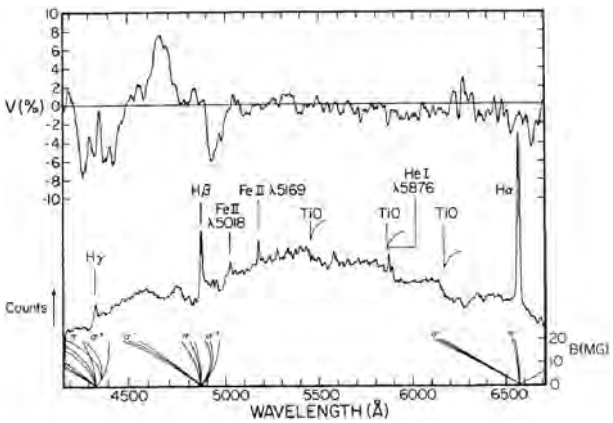

Figure 2. Total flux (bottom) and circular polarization (top) spectra of AM Her obtained during a lapse in accretion. Evident are the polarized, Zeeman-split absorption lines of Hα, Hβ, and Hγ in a photospheric field of 10–20 MG. The TiO features originate on the cool companion star.

The accretion spot

Traditionally, the defining characteristic of an AM Her-type binary has been the strong optical circular polarization (∼5%–30%) of the cyclotron emission radiated in the post-shock flow just above the white dwarf surface. Cyclotron emission is the radiation of high-speed (but non-relativistic) electrons spiraling around magnetic field lines, and one of the very few astrophysical processes which gives rise to a tendency for the electric vector of the emitted radiation to oscillate in a pattern with a net circular component, as opposed to purely linear behavior (linear polarization) or no preferential pattern (unpolarized). The property is so unique to the magnetic synchronized CBs as to earn them the designation *polars*.

The emission spectrum of an electron gyrating in a magnetic field occurs at multiples of the Larmor angular frequency

$$\omega_{\rm L} = \frac{eB}{m_e c}.$$

By analogy with isolated white dwarfs, the strong optical circular polarization of AM Her was initially interpreted to occur near the cyclotron fundamental $\omega_{\rm c} = \omega_{\rm L}$, hence to imply a magnetic field strength $B_1 \sim 200$ MG. However, spectropolarimetric observations during a lapse in ACCRETION (figure 2) revealed the Zeeman signature of a magnetic field of only 10–20 MG in the absorption lines of the hydrogen Balmer series. Since the secondary star was also evident in this low state, the Zeeman spectrum was assigned to the disk-averaged photosphere of the magnetic white dwarf and the high-state polarized light attributed to cyclotron emission in harmonic numbers $5 \lesssim m \lesssim 10$. Subsequently, individual thermally broadened cyclotron harmonics were recognized in high-state spectra, and a polar field strength of 14 MG was inferred[1].

The accretion stream impacts the white dwarf with a

[1] The field pattern is not that of a centered dipole (see table 1).

velocity

$$v \sim \sqrt{2GM_1/R_1} \sim 3000 \text{ km s}^{-1}.$$

In addition to cyclotron radiation, the post-shock flow cools by x-ray bremsstrahlung (free-free emission) with a characteristic temperature $kT_{\rm brem} \sim$ 20–30 keV. The ∼50% of each of these components which is directed downward is absorbed and re-radiated by the white dwarf, giving rise to a third, 'blackbody', component which was predicted by the original models to have a luminosity $L_{BB} \sim L_{\rm cyc} + L_{\rm brem}$, and temperature $kT_{BB} \sim 20$ eV (in the soft x-rays). These ideas were very broadly consistent with early observations. However, a 'reversed' x-ray mode of AM Her was later observed in which the hard and soft x-rays were each strongly modulated on the binary period, but *antiphased* with each other. It was quickly realized that this mode signifies the temporary activation of gas flow onto the opposite magnetic pole. Here, for whatever reason, accretion apparently occurs primarily in the form of dense clumps each of mass $\sim 10^{16}$ g that deposit their kinetic energy deep in the atmosphere of the white dwarf, heating the surrounding photosphere from below to $\sim 10^5$ K. Direct evidence for 'blobby' accretion exists in the form of flickering in the optical and x-ray light curves even in the 'normal' x-ray mode; hence clumps must be more or less important in all flows, a trait which distorts the energy balance from that predicted by the simple model[2].

For the stellar parameters listed in table 1, the observed total high-state luminosity of AM Her, $L \sim 5 \times 10^{32}$ erg s^{-1}, implies an accretion rate

$$\dot{M} = \frac{LR_1}{GM_1} \approx 1 \times 10^{-10}\, M_\odot \text{ yr}^{-1}$$

with the low-state mass-transfer rate down by an order of magnitude or more. The emission is not likely to be uniform over the stream footpoint; a high-density core will be relatively compressed and radiate primarily in the hard x-rays, while a more rarefied sheath will have a greater stand-off shock height and favor cyclotron cooling. Because of the importance of irradiation from above and sub-photospheric heating, the soft x-rays are expected to arise from still larger regions. These ideas are confirmed by a variety of observations which reveal that the spot area as a fraction of the white dwarf surface varies from $f < 10^{-4}$ for the bremsstrahlung emission to $f \sim 0.1$ for the heated polar cap in the near-UV.

The gas stream

In a ROCHE-LOBE filling accretion binary, mass transfer occurs through the inner Lagrangian point $L1$, where the net gravitational force in the co-rotating coordinate frame is zero. Launched by their modest thermal velocity, atoms are quickly ionized by the intense x-ray/UV radiation and accelerate toward the white dwarf under the combined influence of the increasing gravitational field and Coriolis effects. The result is to divert the stream in the prograde direction. In a non-magnetic CB, the gas then loops around the white dwarf, collides with the upstream flow, and diffuses into an ACCRETION DISK surrounding the compact star. In the AM Her-type systems, the magnetic field of the white dwarf begins to dominate the kinematics of the ionized stream at roughly the Alfvén radius, given by

$$\frac{B^2}{8\pi} \sim \frac{\rho v^2}{2}.$$

This transition from ballistic to magnetically controlled regions of the flow occurs at a distance of ~ 5–$10R_1$ above the white dwarf surface. Downstream of the 'coupling region', the plasma clumps are more or less fully threaded by the rapidly increasing magnetic field and approximately follow dipolar trajectories. In general, this includes deflecting the flow out of the orbital plane (see figure 1).

Because the original stream has a non-negligible cross section and coupling occurs over a significant linear distance, different portions of the stream eventually trace different field lines to the surface and the resulting accretion footpoint better resembles an arc than a circular spot. Indeed, gas is already traveling at a speed of ∼1000 km s^{-1} when it encounters the magnetosphere of the white dwarf, so threading is unlikely to be a casual process. When AM Her is in its two-pole mode, the flow apparently branches from the coupling region into a second stream which impacts the magnetic star at a site roughly diametrically opposite the main pole. A more familiar example of the same physics is the twin auroral zones produced by the capture of solar flare particles by the Earth's magnetosphere.

The radiatively-ionized gas stream is also a copious emitter of recombination radiation. Due to the high-velocity, collimated flow, emission lines are broad and highly variable in radial velocity as well as in profile throughout the orbit. In contrast to a typical astrophysical nebula, the line flux from the stream shows $F_{H\gamma} \sim F_{H\beta} \sim F_{H\alpha}$, indicating high optical depths in the dense flow ($N_e \gtrsim 10^{13}$ cm^{-3}).

Table 1. Properties of AM Her

Apparent magnitude, m_V	12–15.8
Period, P	3.09 h
White dwarf mass, M_1	$\sim 0.45 M_\odot$
Companion star mass, M_2	$\sim 0.23 M_\odot$
Companion star spectral type	M4–5
Distance, D	90 pc
Field strength, B_1 (dipolar)	18 MG
Dipole offset, $\Delta R_1/R_1$	0.17
Inclination, i	50°
Dipole colatitude, β	55°
Dipole longitude, ψ	30°

[2] This stochastic flickering should be distinguished from the quasi-periodic oscillations (QPOs) observed in optical light and attributed to oscillations of the shock front.

The stellar components

Cyclotron opacities at high harmonic number are strongly direction dependent and polarization sensitive. For viewpoints near the local magnetic field direction, the emission is comparatively faint and circularly polarized with a sense (+/−) that reflects the field polarity. Perpendicular lines of sight measure strong linear polarization and a source enhanced by the effects of 'cyclotron beaming'. Because the accretion funnel and resulting shock are affixed to roughly radial magnetic field lines on the co-rotating white dwarf, the variations of cyclotron flux and polarization depend on the detailed geometry of the binary: the inclination i, the co-latitude of the magnetic pole β, and the longitude of the field axis relative to the stellar line of centers ψ. When phase-resolved observations of the polarized cyclotron light are combined with radial-velocity studies of the funnel emission lines and stellar absorption lines, these quantities can be more or less uniquely determined and remarkably detailed pictures of the systems constructed. Moreover, comparison of magnetic field strengths in the opposing accretion regions of two-pole systems can be used to deduce the morphology of the field pattern on the white dwarf (e.g. dipole, offset dipole, quadrupole). The entries in table 1 and the scale drawing in figure 1 result from such analyses of AM Her.

In virtually all CBs, the mass of the secondary is sufficiently low that the star's main-sequence lifetime exceeds the age of the Galaxy and it is assumed to be largely unevolved. When the star can be observed directly, such as in a low-accretion state, the measured spectral type is generally consistent with the inferred mass and radius. However, for $M_2 < M_1$, contact between the donor star and its Roche surface can be maintained in the face of mass transfer only if angular momentum is removed from the system. This implies that the orbit must decay with time—and the period decrease—at least until the secondary becomes fully degenerate. Current ideas identify the angular momentum loss mechanism with gravitational radiation plus, for the higher mass-transfer rates of objects with $P \gtrsim 3$ h, magnetic braking by a solar-type wind swept outward along the magnetic field lines of the tidally-locked magnetic companion star. It has been argued that this situation is modified when a strongly magnetic, synchronized primary star is present, since a large fraction of the field lines of the secondary would then terminate on the white dwarf. The reduced number of 'open' lines from the secondary star would reduce the effectiveness of the magnetic braking mechanism. The synchronized systems—including AM Her—do indeed appear to have accretion rates that are systematically lower than non-magnetic CBs at the same orbital period, so it is possible that the magnetic field even affects the period evolution of the binary. At the same time, it is not clear that even two decades of observation is a sufficiently long baseline to evaluate the secular mass-transfer rate of a close binary which has evolutionary timescales ranging from $\sim 10^3$–10^4 yr (for nova eruptions) to nearly 10^9 yr (for orbital period decay). The cause of the low-accretion states, which include an abrupt shut-off in the x-ray flux of AM Her by a factor 7 in just 40 min and can persist for many months, is also unknown.

Spin/orbit synchronism

The primary star of AM Her is subject to an accretion torque

$$N_{\rm acc} \sim \frac{2\pi}{P} R_{L1}^2 \dot{M} \sim 5 \times 10^{33} \text{ dyn cm}$$

where R_{L1} is the distance of the $L1$ point from the white dwarf. Left alone, this would spin up the white dwarf on a timescale $\tau \sim 10^8$ yr. Thus, the accretion torque must be balanced by an offsetting torque which maintains the spin period of the white dwarf equal to the orbital period of the companion. Because any magnetic interaction must be weaker when the component separation is larger (binary younger), it is often felt that an additional, dissipative, torque must act to slow the white dwarf spin rate and initially synchronize the motions. Among the proposed possibilities are magnetostatic interactions with either intrinsically magnetic or nonmagnetic secondary stars, and magnetohydrodynamic effects in which electrical currents are driven through the rarefied plasma medium of the binary. While it is probably not possible to be conclusive in any individual case, empirical clues as to the nature of the interaction(s) are potentially available in the distribution of dipole longitudes ψ for the equilibrium configurations and in possible drifts or slow angular oscillations of the dipole within the binaries. Real-time observations of re-synchronizing magnetic NOVA systems which have been decoupled by nova eruptions also hold promise for elucidating this unique aspect of the physics of AM Her-type systems.

Bibliography

An inkling of the excitement (and confusion) which surrounded the early work on AM Her can be gained from four successive papers in the 15 March 1977 issue of *Astrophys. J.*, including especially: Tapia S 1977 Discovery of a magnetic compact star in the AM Herculis/3U 1809+50 system *Astrophys. J.* **212** 125.

Much of the initial physics and the model for a synchronized system was presented by Stockman H S, Schmidt G D, Angel J R P, Liebert J, Tapia S and Beaver E A 1977 New observations and a slow rotator model of the x-ray binary AM Herculis *Astrophys. J.* **217** 815.

A comprehensive summary of modern research on magnetic as well as non-magnetic CBs is compiled by Warner B 1995 *Cataclysmic Variable Stars* (Cambridge: Cambridge University Press).

Amateur Astronomical Societies

Amateur astronomy has a long and distinguished history. For example, William Herschel, discoverer of the planet Uranus and perhaps the greatest of all observers, began his career as an amateur; in 1845 the third Earl of Rosse built what was then much the most powerful telescope in the world—the Birr Castle 72 in reflector—and used it to discover the spiral forms of the objects we now know to be galaxies. Modern amateurs carry out work which professionals have no time to do, are disinclined to do or are not equipped to do (see AMATEUR–PROFESSIONAL COLLABORATION IN ASTRONOMY). However, an observer working on his own can produce relatively little of value—and this is where amateur astronomical societies play such a major role.

It is important to note that to a considerable degree amateur and professional societies show considerable overlap. For example, in Britain the ROYAL ASTRONOMICAL SOCIETY, the main professional organization, has many amateur members, and in fairly recent times some amateurs have even served as presidents (for example, W H Steavenson, a medical doctor). The BRITISH ASTRONOMICAL ASSOCIATION (BAA) is mainly amateur but also includes many professionals, and past presidents have included several Astronomers Royal. The same situation applies in most other countries. Even the INTERNATIONAL ASTRONOMICAL UNION, the controlling body of world astronomy, has a few amateur members.

Britain has always been prominent in astronomical research, so it may be useful to give a brief account of how the various societies have developed there.

The Royal Astronomical Society, of course, dates back to the 1820s, and one of the earliest presidents was Sir William Hershel (see HERSCHEL FAMILY). There were restrictions on entry; in particular, no women were allowed to become fellows until much later. There was a clear need for a national amateur society, and in the 1880s came the Liverpool Astronomical Society, which mushroomed into an international organization. Then, suddenly, it collapsed, partly because of financial problems and partly because of poor administration. It was then that the BAA was formed; its first meeting was held in London in 1890.

From the outset, the BAA set out to be an observational society, and different sections were formed, each controlled by an experienced director. For example, one section was devoted entirely to the observation of the planet Jupiter, and regular reports were issued, both in the Association's monthly *Journal* and in the specialized *Memoirs* (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS). It is probably true to say that these publications represent the best and most continuous series of observations of Jupiter available, and the work continues today, although it is true that the space-probe results have to some extent superseded any Earth-based observational program. Other sections dealt with the Sun, the Moon, Mars, comets, variable stars and so on.

Initially, the BAA was frowned upon by the Royal Astronomical Society, but it soon became clear that there would be no conflict of interest, and for many years now the two societies have been based in the same building at Burlington House in Piccadilly. Various branches of the BAA were established, although one by one they decided to break away and become totally independent. Only the New South Wales Branch in Australia remains today.

There were no restrictions on entry, and there have been some very young members[1]. However, at one point it was felt that there could be a need a for society catering entirely for young people. A proposal for a junior section was put to the BAA Council but was not accepted. This led to the formation of the Junior Astronomical Society (JAS), and it was assumed that young enthusiasts would join the JAS and then move on to the BAA. This did happen initially, but in the 1960s the JAS decided to become a parallel organization; it is now known as the Society for Popular Astronomy.

There can be no doubt that the BAA has been an extremely successful organization, and for many years it was in a class of its own. To some extent this is still true, but it was centered mainly in London, and there was a need for local societies also. By now almost every major city and town in the British Isles has its own society, and many of these are affiliated to the BAA.

One great advantage of a local society is that it can set up an observatory. Public observatories in Britain are rare, and local societies have been invaluable in filling this gap. Some are extremely well equipped and capable of carrying out work of professional standard. Moreover, many young enthusiasts who begin by joining their nearest society go on to become professional astronomers. School societies flourish, although it is true that they depend on the presence of a least one dedicated member of staff. A few schools even have their own radio astronomy observatories (Taunton School in Somerset, for example).

There are many amateur societies in Scotland and also in Ireland. Active societies also exist in the Channel Islands and the Isle of Man. All these various societies are linked and work together to their mutual benefit. Moreover, many of them publish their own regular journals, and their activities and results are reported in national periodicals such as *Modern Astronomer* and *Astronomy Now*.

The situation in the United States is much better from the public observatory point of view, and amateur societies are very numerous indeed. Of particular importance is the AMERICAN ASSOCIATION OF VARIABLE STAR OBSERVERS (AAVSO), which is the largest organization of its kind anywhere in the world and produces a vast number of important observations. Predictably it is made up of both amateurs and professionals, but for sheer visual work it is the amateurs who are the most prolific, especially now that they can use electronic devices such as CCDs and

[1] If I may add a personal note: I was elected in 1934, at the age of 11, when the President was the then Astronomer Royal, Sir Harold Spencer Jones. I became President exactly 50 years later.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can produce results which will satisfy any professional researcher. To list all the other major societies would take many pages, but particular mention should be made of the ASTRONOMICAL SOCIETY OF THE PACIFIC, which has many amateur members.

Canada has two main societies: the Canadian Astronomical Society (mainly professional) and the ROYAL ASTRONOMICAL SOCIETY OF CANADA (part professional, part amateur). The same sort of situation applies in Australia and in New Zealand. Amateur societies flourish in almost all European countries and in Russia. Japan, of course, has a great tradition of amateur observational work, and here too there are both national and local organizations.

Naturally, all societies—national and local—have their regular meetings, and these are invaluable, because it is often possible to invite well-known speakers who will be able to give advice and encouragement.

Financial considerations are always very much to the fore. Subscription rates are kept as low as possible, but bills have to be paid, particularly if premises of any kind are involved. Local authorities will often help, though others are much less cooperative (in Britain, one society was recently forced to abandon its observatory because the council decided to increase the ground rent to an impossible amount). However, even a society which has no headquarters or observatory will almost certainly have members who possess telescopes of their own and will make them available to newcomers. By now there are also some ambitious societies which are setting up their own planetaria—and surely a planetarium is the best possible educational aid. There are plenty of these in the United States and a few in Britain, notably the planetarium now being erected near Chichester, in Sussex, by the South Downs Astronomical Society.

There has been one setback in recent years. It was proposed to form an international amateur organization to correlate the work of societies all over the world, and during the 1960s, at a General Assembly of the International Astronomical Union, such an organization was actually set up: the International Union of Amateur Astronomers (IUAA). It has issued some publications and has held several meetings in different countries, but it has to be admitted that it has never been a real success, again for reasons of financial constraint. In the future it is hoped that it will be extended and that it will play a really useful role, but it is difficult to organize, and much remains to be done.

Meanwhile, amateur astronomical societies exist in virtually all countries. Their value cannot be overestimated, and today, in the Space Age, their role is even more important than it has been in past years.

Amateur–Professional Collaboration in Astronomy

It is probably true to say that, in most branches of science, the day of the amateur is over. No modern amateur can expect to undertake important research work in physics, for example, where elaborate and expensive equipment is essential; neither can he expect to make a major theoretical discovery, because a very rigorous training is needed. True, there is still scope for some good amateur work in geology and paleontology, but it is with astronomy that the amateur really comes into his own.

A century ago, there were various branches of astronomy in which the amateur reigned supreme. The best observations of the Moon and the surfaces of the planets were made by amateurs, and this was still true until not long before the Second World War. It is also worth remembering that in 1845 the 3RD EARL OF ROSSE, with no expert help, built what was then much the most powerful telescope ever constructed—the 72 in reflector at Birr Castle, in Ireland—and used it to discover the forms of the objects then called spiral nebulae, and now known to be external galaxies. (It is pleasing to note that, after a long period of neglect, the Birr telescope has now been restored to full use, even though it is of course by no means the equal of a modern telescope of the same aperture.)

Around 1900, photography took over from the eye for most branches of astronomy. Today photography is itself being superseded by electronic aids, such as CHARGE-COUPLED DEVICES (CCDs), which are far more sensitive. No longer does the astronomer have to spend hours in a cold, dark dome, making sure that his telescope is still firmly fixed on its target object; he need not be in the dome at all, or even in the same country. Everything comes through on a television screen. This has obvious advantages, quite apart from comfort, but it does mean that the professional astronomer seldom or never actually looks through a telescope, and he has no need to have a practical knowledge of the sky. It is almost certainly true to say that few professional astronomers can recognize more than half a dozen constellations[1]. Some amateurs, on the other hand, have a truly encyclopedic knowledge of the sky and can identify many hundreds of stars with no trouble at all.

Amateur equipment has changed markedly in the recent past. Fifty years ago the average amateur used a telescope of moderate aperture—say up to 18 in for a REFLECTOR—and was more concerned with visual work than with photography. Today, the well-equipped amateur has become skilled in electronics. Using a CCD with, say, a 15 in telescope, a modern amateur can produce results which would match those of major professional observatories in the immediate post-war era.

[1] I well remember one well-known professional astronomer telephoning me to say that he had just found a nova, and was about to notify the Royal Observatory. In fact, he had made a completely independent discovery of the planet Saturn.

There are, of course, some amateurs who do not use telescopes at all. Naked-eye work can be useful, particularly with regard to meteors and aurorae (see the article on NAKED-EYE ASTRONOMY). However, binoculars can be very valuable indeed (see BINOCULAR ASTRONOMY), notably in the hands of those amateurs who spend their time in searching for comets and novae. George Alcock, an English schoolmaster, has now discovered four comets and three novae, all with the aid of powerful binoculars. He 'sweeps' the sky, and his knowledge of the star patterns is so good that he can recognize a newcomer at a glance. He is not alone in this; there have been many recent comet discoveries by amateurs—including the two most recent 'great' comets, Hyakutake of 1996 and Hale–Bopp of 1997.

One of the outstanding amateurs of the present day is an Australian clergyman, the Rev. Robert Evans. He uses a portable telescope and scans external galaxies to search for supernovae. So far he has found more than 20. A supernova is a colossal stellar outburst, marking the death of a star; in our own Galaxy no naked-eye supernovae have been seen since the year 1604, but they do occur in the outer systems, many millions of light-years away. Nobody can tell when a supernova will burst forth, and it is important to obtain observations as early as possible, so that the advance warnings given by amateurs such as Evans are of vital significance. Searches of this kind are now being carried on by many amateurs, with great success. Some observers, such as Evans, work visually; others use photography or CCD equipment. It is hardly necessary to add that contributions of this kind are very warmly welcomed by professional astronomers.

Ordinary novae can also be identified by amateurs, with their knowledge of the sky, and in recent years several minor planets or asteroids have also been found in the same way. Clearly it is essential to give prompt notification of a discovery. There are centers in many countries, but every confirmed discovery is announced by the telegram service of the INTERNATIONAL ASTRONOMICAL UNION (IAU), which has world-wide coverage. It is also true, of course, that many alleged 'discoveries' turn out to be false alarms, and every effort is made to filter these out before they waste valuable observing time.

Variable-star work has always been a major part of amateur observational astronomy. VARIABLE STARS are of many kinds. Some, such as the Cepheids, are as regular as clockwork; others, such as the Mira stars, differ in behavior from one cycle to another; yet others are completely irregular, so that one can never tell what they will do next. There are so many variable stars that professional astronomers cannot hope to keep track of them all, and great reliance is placed on amateur work. Much of this is purely visual. The procedure is to compare the variable with nearby stars which do not fluctuate. With a little practice it is not difficult to make estimates correct to one-tenth of a magnitude, and for most purposes this is good enough. Using photometers, it is possible to obtain estimates which are far more accurate that this, and it is true that most modern amateurs who are

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

seriously concerned with variable-star research do have photometric equipment. A really large telescope is not essential; a reflector of, say, 6–12 in aperture will give its owner more work than he can possible handle. The results are correlated by organizations such as the Variable Star Section of the BRITISH ASTRONOMICAL ASSOCIATION and the AMERICAN ASSOCIATION OF VARIABLE STAR OBSERVERS.

There are some variables which are within naked-eye range; such is Gamma Cassiopeiae, in the W of Cassiopeia, which is an unstable 'shell' star. It is usually just below the second magnitude, but in the late 1930s brightened up abruptly by more than half a magnitude, subsequently sinking to below magnitude 3 before returning to its normal state. The early observations of the 1930s outburst were amateur, and one never knows when the same will happen again. Many dozens of variables can be followed with binoculars, and accurate light curves can be drawn up.

So far as the Moon is concerned, amateur work led the way for many years. Before the possibility of space missions, most professionals were concerned only with lunar movements, and amateur maps were the best of the time. There was also the chance of making really interesting discoveries, such as formations in the libration areas, near the edge of the Earth-turned hemisphere. When the Russians sent up their first circumlunar probe, Lunik 3, in 1959, they obtained photographs of the far side, which is never visible from Earth because it is always turned away from us; amateur maps were used to correlate the Lunik 3 results with the Earth-turned regions. However, the situation has changed now. Space missions have enabled us to obtain detailed charts of the entire Moon, and amateur cartography has lost its value, but there is still work to be done. Although the Moon is more or less inert, there are occasional very brief, obscure outbreaks which are known as TLP or transient lunar phenomena. Presumably these are due to mild release of gases from below the crust, and they have been seen so often, and by so many reliable observers (including a few professionals), that it is difficult to question their reality. Confirmation of their reality was obtained in 1999 by A Dolfus using visual and polarimetric measurements. Dedicated amateurs are studying them, and the results are of great interest.

Occultations of stars by the Moon are still useful, and amateurs are expert at timing them. There are also occultations of star by asteroids, and because the tracks are so narrow the amateur has a great advantage; he can take a suitable telescope to just the right place at just the right time, which the professional cannot do. Important measurements of asteroid positions and dimensions have been made in this way.

Amateur solar work is also becoming of increasing importance. Casual tracking of sunspots is interesting, but for real solar research a considerable amount of complex equipment is needed. H-alpha filters are now common, and there are a few excellent spectrohelioscopes; indeed one leading British amateur solar researcher, Commander Henry Hatfield, has gone so far as to build his entire house round his spectrohelioscope. Amateur observations of flares and associated phenomena are used to supplement the work carried out at major professional observations.

Now that we have the amazingly detailed views of the planets from the various space missions, it might be thought that amateur planetary observation has lost all its value. This is most emphatically not the case. For example, at the present time (2000) Saturn is not being monitored by any probe. Major outbreaks do occur there from time to time, and many of these are first seen by amateurs; for example, the brilliant white spot of 1933 was discovered by an amateur, W T HAY, probably best remembered by the general public as Will Hay, the stage and screen comedian. The latest white spot was also first seen by an amateur, Wilber; only later was it imaged by the Hubble Space Telescope. It is very likely that the next violent outbreak on Saturn, whenever it occurs, will also be an amateur discovery, and early notification means that professional equipment can be used as soon as possible. Jupiter is another favorite target for amateurs, because the surface features are always changing; on the Giant Planet there is never any lack of something new to see.

For Jupiter, and perhaps Saturn, a modest telescope can be used with success. Mars is much more of a problem, because a high magnification is necessary, but when the planet is near opposition the amateur with, say, a 12 in or 15 in telescope can help in monitoring cloud phenomena and the behavior of the polar caps—particularly if he has access to electronic equipment.

Even with remote Pluto there is scope. Very occasionally Pluto occults a star, and when this last happened amateur measurements were very valuable; pre-occultation fading of the star confirmed that Pluto does have an extensive if highly tenuous atmosphere.

In astronomy, as in all other sciences, cooperation is of paramount important. There is no point in making an observation unless other workers hear about it. The controlling body of world astronomy is the IAU, which really is international—and remained so even during the worst part of the Cold War. There are some amateur members of the IAU, and there have even been amateur officials. General Assemblies are held every 3 years, in different countries; that of 2000 will be in England (Manchester), following 1997 (Holland) and 1994 (Argentina). During the 1960s an attempt was made to form an analogous amateur organization, the International Union of Amateur Astronomers. It does exist, but it would be idle to pretend that it has been as successful as had been hoped, and better organization is needed. Meanwhile, all countries have their national societies—in Britain, for example, the British Astronomical Association, which is mainly amateur and has an observational record second to none. Most major towns and cities of the world have their own societies, and there is a pleasing amount of cooperation, both national and international (see also AMATEUR ASTRONOMICAL SOCIETIES).

All in all, it is fair to say that amateur astronomers undertake work which the professional does not wish to do, does not have the time to do or genuinely cannot do. It is also true that amateur work is valued and warmly welcomed and that the amateur astronomer is every bit as important now as he has been in the past.

Ambartsumian [Ambarzumjan], Viktor Amazaspovich (1908–96)

Astrophysicist, born in Armenia, professor at the University of Leningrad and at Erevan, founded the Byurakan Astronomical Observatory. He applied an original and creative scientific imagination to a range of observational phenomena in astronomy. He suggested that T Tauri stars are very young and that loose stellar associations are dissociatiating. He made the connection between the various energetic phenomena in galaxies (jets, high-speed motions, bright ultraviolet luminosities, etc) as pointing to energetic sources at the centers of galaxies, now identified as massive black holes.

American Association of Variable Star Observers

The largest organization of variable star observers in the world, with over 1000 members in more than 40 countries. Its database contains over 9 million observations of variable stars. The organization's headquarters are in Cambridge, Massachusetts.

It was founded in 1911 by amateur observer William Tyler Olcott. Inspired by a talk at the 1909 meeting of the American Association for the Advancement of Science, Olcott began to send his observations of variations in stellar brightness to Edward Pickering at Harvard College Observatory.

American Astronomical Society (AAS)

Founded in 1899, the AAS is a non-profit scientific society created to promote the advancement of astronomy and closely related branches of science. Its membership consists primarily of professional researchers in the astronomical sciences, but also includes educators, students and others interested in the advancement of astronomical research. About 85% of the membership is drawn from North America. The AAS operates in five major areas: Publications, Meetings, Education, Employment and Public Policy. Its headquarters are in Washington, DC.

The AAS research journals, *The Astrophysical Journal* and *The Astronomical Journal*, appear in both print and electronic formats. *The Bulletin of the American Astronomical Society* reports the latest institutional developments and documents the content of the meetings held by the AAS and its five Divisions. AAS meetings, held twice a year, provide a forum for the presentation of scientific results.

Anaxagoras of Clazomenae (*c*. 500–*c*. 428 BC)

Born in Clazomenae, now Turkey, an Athenian philosopher who correctly explained the phases of the Moon and eclipses of the Moon and the Sun. He believed, like the atomists, that the heavens and the Earth were brought into existence by the same processes and composed of the same particles, but also recognized that further agencies were required to create their motions, identifying that agency as 'mind' (*nous*). He was impeached for impiety, for claiming that the Sun was a red-hot stone, ignited by its motion, and larger than the Peloponnesus, but not a god, and that the Moon was Earth that reflected the Sun's light. He was banished to Ionia.

Anaximander of Miletus (*c*. 611–*c*. 547 BC)

Greek philosopher, born in Miletus, pupil of THALES. Believed that the Earth was a cylinder with a diameter three times its height, unsupported, at the center of the universe. We live on the top end of the cylinder. His theory of the universe was that objects are formed from a vortex process by which light objects were flung out to their periphery. This separated hot and cold, moist and dry, and Earth and ether. He thought the Moon and Sun and stars were self-luminous wheels of fire. He is credited with producing the first map of the Earth, and with being the first to speculate on the relative distances of the heavenly bodies.

Anaximenes of Miletus (*c*. 585–*c*. 525 BC)

Greek philosopher, born in Miletus, pupil of ANAXIMANDER. The first Greek to distinguish clearly between planets and stars, Anaximenes conceived the idea that the stars were fixed like nails on a crystalline sphere, which he apparently believed was a hemisphere and rotated like a hat on a head. He believed the primary substance of the universe was air, which could form the other elements of water, earth and fire by compression and rarefaction. For example, the Earth was made from dense air, which, vaporized, made the Sun, Moon and planets. Credited with the invention of the gnomon, the central shadow-casting stem of a sundial; he certainly appears to have had an interest in sundials and exhibited at Sparta the sundial called Sciotherion.

Andromeda

(abbrev. And, gen. Andromedae; area 722 sq. deg.) A northern constellation that lies between Perseus and Pegasus, and culminates at midnight in early October. It is named after the daughter of King Cepheus and Queen Cassiopeia in Greek mythology, who was rescued by Perseus from being sacrificed to the sea monster Cetus, and is usually shown on early celestial charts as a chained maiden. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A rather inconspicuous constellation, the brightest stars in Andromeda are α Andromedae (Alpheratz or Sirrah), magnitude 2.1, β Andromedae (Mirach), also magnitude 2.1, and γ Andromedae (Almach), a fine orange (K3) and bluish-white (B8) double star, magnitudes 2.3 and 5.0, separation $10''$. All other stars are of the third magnitude or fainter. α Andromedae, which marks the north-east corner of the Square of Pegasus, was originally designated δ Pegasi. α, β and γ Andromedae form a slightly curved line of stars, pointing diagonally away from the Square.

To the north-west of β Andromedae are two fourth-magnitude stars, μ and ν Andromedae, which are at almost a right angle to the line joining α, β and γ. About 1° west of ν lies the Andromeda Galaxy (M31, NGC 224), the largest spiral galaxy in the Local Group, which, at a distance of 2.7 million light-years, is just visible to the unaided eye as a faint misty patch.

Other interesting objects in Andromeda include the Mira-type variable stars R Andromedae (range 5.8–14.9, period about 409 days) and W Andromedae (range 6.7–14.6, period about 396 days), NGC 752, an open cluster of several dozen stars fainter than eighth magnitude, and NGC 7662, a ninth-magnitude planetary nebula.

See also: Andromeda Galaxy.

Andromeda Galaxy

The Andromeda galaxy is the closest SPIRAL GALAXY to the MILKY WAY, just visible to the naked eye on a dark night as a faint smudge of light in the constellation Andromeda. The earliest records of the Andromeda nebula, as it is still often referred to, date back to AD 964, to the 'Book of the Fixed Stars' published by the Persian astronomer AL-SÛFI. The first European to officially note the Andromeda nebula was Simon Mayer, a German mathematician and astronomer, who was not aware of Al-Sûfi's earlier work. The object is number 31 in the famous MESSIER CATALOG, which dates back to the 18th century, and is therefore often referred to as M31. Another alias for the Andromeda galaxy is NGC 224, since it is number 224 in the NEW GENERAL CATALOG (NGC) compiled by DREYER in 1888. Modern measurements based on Cepheid variables place M31 at a distance of 740 kpc or about 2.4 million light-years. This makes it the closest spiral galaxy to the Milky Way. It is the dominant member of the LOCAL GROUP, and as such it has and continues to fill an important role in studies of galaxy structure, evolution and dynamics, stellar populations, star formation and interstellar medium. Crucial historical developments include HUBBLE's work in the 1920s on the distance to M31, which proved that galaxies outside our own Milky Way exist, and BAADE's work in the 1940s on stellar populations which led to the concepts of old (population II) and young (population I) stars. Many small companion galaxies believed to be associated with M31 have been identified, some only in the past year. They are M32 (low-luminosity elliptical), NGC 147, 185 and 205 (dwarf ellipticals), IC 10 (dwarf irregular), LGS 3 (transition object between dwarf irregular and dwarf spheroidal) and And I, II, III, V and VI (dwarf spheroidals). It is likely that more faint companions remain to be discovered. Figure 1 shows an optical image of the Andromeda galaxy.

Figure 1. Optical image of the Andromeda galaxy and two of its nearby elliptical companions, M32 (below center) and NGC205 (upper right corner). The image measures 100′ on a side, corresponding to 21.5 kpc. Based on photographic data obtained using the Oschin Schmidt Telescope on Palomar Mountain. The Palomar Observatory Sky Survey was funded by the National Geographic Society. The Oschin Schmidt Telescope is operated by the California Institute of Technology and Palomar Observatory. The plates were processed into the present compressed digital format with their permission. The Digitized Sky Survey was produced at the Space Telescope Science Institute (ST ScI) under US Government grant NAG W-2166. Morphology, mass and stellar content

The Andromeda galaxy is a large, early-type spiral of HUBBLE CLASSIFICATION Sb, luminosity class I–II. It has a prominent central bulge of stars with an effective radius of 2 kpc, which extends smoothly into an extended flattened spheroidal component of old stars. As in most spiral galaxies, in addition to the bulge or spheroidal component, there is a thin disk of stars and gas with superposed spiral arm structure. The combined light from the disk stars declines exponentially with distance from the center, as is common for spiral galaxies. The disk scale length is about 5–6 kpc, and M31 is some 50% larger than our Milky Way Galaxy and about twice as luminous. The disk becomes bluer at larger radial distance from the center, and this could be caused by a relatively larger fraction of younger stars there, or a lower abundance of heavy elements. Abundance determinations of oxygen, nitrogen and sulfur in the interstellar medium of M31 do indeed show an overall decrease in these elements compared with hydrogen with increasing radial distance.

The SPIRAL ARM structure of M31 has been difficult to determine, owing to its orientation on the sky. Spiral arm segments show up clearly in the distributions of young massive stars and various interstellar medium tracers such as ionized, neutral and molecular hydrogen gas, and dust, but it has not been possible to link the spiral arm segments into an unambiguous grand design spiral structure. A further complication is that the interaction with the close small elliptical companion M32 seems to have distorted the spiral arms as well. The outer stellar and gaseous disks, beyond about 20 kpc, bend out of the principal plane, producing a phenomenon known as warping. Given its bulge size and luminosity, there seems little doubt that M31 is an earlier-type spiral than our Milky Way. For example, the total number of GLOBULAR CLUSTERS, which has been shown to be related to the bulge or spheroid luminosity, is probably between 400 and 500 in M31, almost a factor 3 larger than for the Milky Way. The velocity dispersion of the stars in the bulge of M31 is about 155 km s^{-1}, while for the Milky Way this is 130 km s^{-1}.

From its H I rotational velocity out to 30 kpc radius, one can infer that M31 has a mass of at least 3×10^{11} solar

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

masses, but the total mass will probably be much higher depending on the unknown radial extent of a DARK MATTER halo, a common component in spiral galaxies inferred from the high rotational velocities of gas clouds in the far outer disks. The timing argument for the Local Group implies a mass of a few times 10^{12} solar masses for M31. Given these figures, dark matter must strongly dominate over the mass implied by the visible stars and gas.

The stellar populations in M31 are discussed in the article M31: THE OLD STELLAR POPULATIONS, so a brief summary will suffice here. The bulge and spheroid population is old, although the considerable spread in metal abundances of the stars in the bulge and also the outer halo implies a more complicated formation scenario than a very rapid initial collapse. There is no current star formation in the inner bulge, contrary to the situation in the Milky Way. The properties of the globular clusters of M31 are similar in many ways to those of the Milky Way, i.e. the globular clusters are old, show a range of metal abundances and the same overall correlations between velocity dispersion and luminosity, central and average surface brightness as the Galactic globular clusters. A small number of young massive clusters is found in the disk, at about 10 kpc from the center. Such clusters are common in late-type galaxies, such as M33 and the Magellanic Clouds, but apparently rare in early-type spirals. These could be the progenitors to (low-mass) globular clusters. Interestingly, these objects are mostly concentrated in the tidally disturbed SW spiral arm, and they may be similar to young blue clusters observed in interacting galaxies.

One of the advantages of the close distance of M31 to us is that it enables unique experiments. One of these is the recent attempt to detect MICROLENSING towards M31 bulge stars to constrain the nature of the dark matter. While M31 is too distant to resolve most of its light in individual stars, microlensing can in principle still be detected as a brightening of individual pixels on the detector, if one star of the many contributing to the brightness of that pixel is being lensed by a dark object in M31's halo. Several of these studies are now underway, thereby extending the ongoing microlensing observations of the Galactic bulge and of the Magellanic Clouds.

The central region

The Andromeda galaxy does not contain a particularly active nucleus at its center, but there does appear to be a BLACK HOLE of about 3×10^7 solar masses there. The evidence for this comes from measurements of the stellar velocities close to the center both with the HUBBLE SPACE TELESCOPE and from the ground. The morphology of the central region is quite surprising, with two peaks in the brightness distribution separated by 0.5 arcsec. The currently favored interpretation is that this apparent double nucleus is actually caused by a single eccentric disk of stars orbiting the black hole. The brighter of the two 'nuclei' would then be caused by stars piling up near the apocenter of the eccentric disk, where their speeds are low, while the fainter 'nucleus' would be due to the increase in density towards the center.

The lack of strong nuclear activity associated with the black hole could be due to the general lack of interstellar medium in the M31 bulge. No H I or CO has been detected within 1 kpc from the center, although there are some dust clouds seen in projection against the bright stellar continuum. A faint diffuse 'spiral disk' is seen in ionized gas, with a radial extent of about 500 pc, but it only contains a small amount of mass, perhaps as little as 1500 solar masses total. This gas possibly originates from mass lost by low-mass evolving stars in the form of stellar winds. The lack of activity also manifests itself in the weak level of radio continuum emission, about a factor of 10 less than for the Galactic center.

Star formation and interstellar medium

As the closest nearby spiral, M31 has been a prime target for exploring the properties of various gaseous phases of the interstellar medium and massive stars, and the connections between them. The spatial distribution of all these components, be they neutral or ionized gas, dust or OB stars, is very similar: there is a general lack of gas and young stars in the inner several kpc, some gas and star formation in spiral arms 3–5 kpc from the center, strong concentrations in an annulus between 8 and 12 kpc and modest concentrations in arms out to 15 kpc. Beyond this, the H I disk continues to show spiral structure out to 25 kpc or so, with weak ongoing STAR FORMATION in selected regions. Star formation rates can be estimated from the distribution of ionized gas (H II regions and diffuse ionized gas), which requires hot, luminous, hence massive and young, stars to ionize it, far-infrared emission radio continuum emission and UV light. In addition, the proximity of M31 allows detection of individual OB stars and of evolved tracers of young massive stars such as WOLF–RAYET STARS and LUMINOUS BLUE VARIABLES. All these tracers indicate that the overall level of star formation activity in M31 is quite low, about $\approx$ 0.3–0.5 solar masses yr^{-1}, compared with the Milky Way and other spirals, such as M33. In addition, M31's largest star-forming complexes appear modest compared with those found in other galaxies.

The mass of atomic hydrogen gas is about 4×10^9 solar masses, while that of molecular hydrogen is more than a factor of 10 lower; the uncertainty in the conversion factor of the CO line flux to molecular gas mass makes the latter estimate rather inaccurate, but the low molecular hydrogen surface density is consistent with the overall low rate of star formation in M31. There is some evidence for the presence of very cold molecular gas in M31, which might have further implications for the total molecular gas mass. M31 was one of the first external spirals where a widespread distribution of ionized gas outside of traditional H II regions was detected. This diffuse ionized gas, also referred to as warm ionized medium, is the dominant component, in terms of mass and spatial extent, of ionized gas in galaxies. It requires a large amount of

Dirac House, Temple Back, Bristol, BS1 6BE, UK

energy to remain ionized, and its widespread distribution implies that the morphology of the interstellar medium has to be very porous, or else the ultraviolet photons from OB stars could not travel far from their origins before being absorbed.

Information on COSMIC RAYS and the magnetic field distribution in M31 has been obtained from detailed radio continuum observations at several frequencies. The radio continuum is strongly dominated by non-thermal synchrotron emission, stemming from highly relativistic electrons spiraling in a magnetic field. Information on field strength and direction can be inferred from the intensity of the emission, the polarization vectors and the rotation measures observed towards extragalactic background sources. The large-scale magnetic field extends from 5 kpc interior to the star formation annulus to as far as 25 kpc from the center. The main field organization is toroidal, aligned along the annulus, with some evidence for a poloidal component extending into the halo. The structure of the field appears to be that expected for an even-mode DYNAMO.

Outlook for the future

There is no question that the Andromeda galaxy will continue to play a central role in future investigations of the morphology and evolution of galaxies, just as it has in the past. With the next generation of telescopes, on the ground and in space, we can expect new results in many areas, such as microlensing studies, high-resolution maps of all the interstellar medium components, abundance measurements in individual stars and further unraveling of the star formation history of M31's disk and bulge.

Bibliography

An extensive overview of the characteristics of the Andromeda galaxy, providing references to all relevant papers from before 1992, is given in the monograph

Hodge P W 1992 *The Andromeda Galaxy* (Dordrecht: Kluwer)

Photographs indicating the positions of open clusters, globular clusters, OB associations and dust clouds in the Andromeda Galaxy are presented in

Hodge P W 1981 *Atlas of the Andromeda Galaxy* (Seattle, WA: University of Washington Press)

A good impression of the morphology of H II regions and diffuse ionized gas can be obtained from

Anglo-Australian Observatory

The Anglo-Australian Observatory (AAO) operates two optical telescopes at Siding Spring Mountain, the 3.9 m Anglo-Australian telescope and the (1.2 m) 47 in UK Schmidt Telescope. These telescopes are located beside the spectacular Warrumbungle National Park outside Coonabarabran in New South Wales, 450 km northwest of Sydney.

The Anglo-Australian Telescope (AAT) was established after representations had been made to the Australian and British governments in the mid-1960s. The agreement was secured in an act of the Australian Parliament, The Anglo-Australian Telescope Agreement Act, 1970. Each government contributes equally in return for equal use of the telescopes. The AAT was inaugurated in 1974.

The UK Schmidt Telescope (UKST) is a special purpose survey telescope. Its initial task was the first detailed photographic survey in blue light of the southern skies. Other major projects have since been undertaken, and more are in progress. The UKST recently began an Hα survey of the southern Milky Way and Magellanic Clouds.

The AAO spends 15% of its budget each year on new instruments and associated software and detectors.

Over the past decade, the AAO has pioneered the use of optical fibres in astronomy. The recently completed 2dF uses optical fibers to enable 400 objects to be analysed at once. The 2dF is being used in a very ambitious project to map a very large volume of the universe. The 2dF Redshift Survey aims to measure the redshifts of 250 000 galaxies over two years. In parallel, there is a similar redshift survey of 30 000 quasars.

The AAO has recently begun building a fiber positioner similar to the 2dF for the EUROPEAN SOUTHERN OBSERVATORY's Very Large Telescope (VLT).

David Malin, an astronomer at the AAO, has developed techniques to make astronomical color photographs from plates taken in three separate colors. These beautiful images have earned recognition as among the finest in the world.

Angstrom

A unit of length frequently used to describe the wavelength of light. It is named after the Swedish physicist Anders Jonas Ångström (1814–74), a founder of spectroscopy. It is equal to 10^{-10} meters (i.e. one ten thousand millionth of a meter) and is denoted by the symbol Å. Most of the visible spectrum lies in the wavelength range 3900 to 7500 Å.

See also: light, wavelength.

Angular Momentum

A property of rotating bodies or systems of masses which is dependent upon the distribution and velocities of the masses about the axis of rotation. The angular momentum of a single particle of mass, m, moving in a circular orbit of radius, R, at velocity, v, is given by mvR. Angular momentum is a conserved quantity, in other words, the total angular momentum of a system is constant. Thus if a large slowly rotating gas cloud contracts, its rotational velocity must increase to conserve angular momentum; as it contracts, therefore, it spins more rapidly. Appropriate SI units for angular momentum are kilogram meters squared per second (kg m^2 s^{-1}). The conservation of angular momentum is of central importance to such questions as star formation, the origin of planetary systems, etc.

Anomalous Cosmic Rays

The anomalous cosmic rays are an ionic component of the cosmic-ray flux which is observed, in the heliosphere, to be significant at energies ranging from 20 MeV to more than 500 MeV. They consist of a number of ion species ranging from hydrogen to beyond neon, but anomalous carbon is significantly underabundant. The highest kinetic energy reported for this component is more than 1.6 GeV. Observations from detectors on board heliospheric spacecraft show that their intensity continues to increase out to the maximum distance reached by current spacecraft, indicating that they are accelerated in the outer solar system. They were first seen in the early 1970s and were initially called anomalous cosmic rays because of their unusual composition and because their spectrum was unlike that of the already well-known galactic or solar cosmic rays. This name has stuck, even though we now know much more about the nature and origin of these particles.

In 1974 it was suggested that the anomalous component was the result of the acceleration, in the heliosphere, of recently ionized interstellar neutral atoms (see also COSMIC RAYS: PROPAGATION IN THE HELIOSPHERE). The neutral atoms stream into the solar system from the interstellar medium and are then ionized by solar ultraviolet radiation or by charge exchange with the SOLAR WIND. This hypothesis explained very nicely the unusual composition of the anomalous component, since only initially neutral interstellar particles can enter the heliosphere to participate in the process. For example, carbon ions, which are nearly fully ionized in the interstellar medium and hence are mostly prevented by the interplanetary magnetic field from entering the solar system, are notably depleted in the anomalous cosmic rays. More-recent observations have established that the bulk of the anomalous cosmic rays are indeed singly charged, as expected in this picture.

Later, in 1981, it was pointed out that many features of the anomalous component could be explained if the major part of the acceleration of the newly ionized particles occurs at the termination shock of the solar wind, by the mechanism of diffusive shock acceleration. Subsequent sophisticated numerical simulations carried out in the mid-1980s clearly showed that energetic, singly charged particles could be accelerated very efficiently at the termination shock. The essential observed features of the spectrum and spatial gradients could be explained very naturally in terms of this picture. This picture of acceleration of newly ionized interstellar neutrals and subsequent acceleration to high energies at the termination shock of the solar wind is now the standard paradigm (see also SOLAR WIND: ENERGETIC PARTICLES). This paradigm is illustrated schematically in figure 1, which shows the incoming neutral atoms, their ionization and the subsequent acceleration at the termination shock of the solar wind. A typical observed anomalous cosmic-ray spectrum (with the solar and galactic contributions removed) is shown in figure 2(*a*).

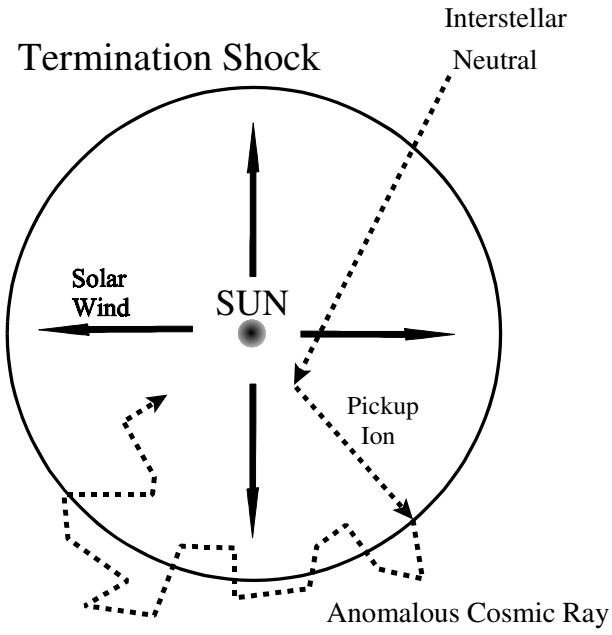

Figure 1. Schematic illustration of the heliosphere and the acceleration of the anomalous cosmic rays. Shown are the incoming interstellar neutral, the ionization to form a pickup ion and the subsequent acceleration and propagation of the anomalous cosmic ray.

Acceleration

The acceleration of the anomalous cosmic rays from low energies to the typical observed energies of ≈200–300 MeV must occur in less than a few years, because otherwise further electron loss would occur owing to interactions with ambient gas, and they would not be singly charged. In fact, independent of the acceleration site or model, the observed fact that anomalous cosmic-ray oxygen particles at ≈160 MeV are still mainly singly charged implies that the total path length they have traversed since being accelerated is less than 0.2 pc. Given that they cannot travel in a straight line because of the ambient, irregular magnetic fields, this fact requires that the anomalous cosmic rays must be locally accelerated. At their observed speed, this implies that the time since acceleration is less than a few years. Diffusive shock acceleration at the quasi-perpendicular termination shock of the solar wind, which accomplishes the acceleration to ≈200 MeV in about a half a year, is the only process known at present which can accomplish the acceleration in the allowed time. In particular, the commonly invoked second-order Fermi acceleration mechanism, involving fluctuating electric fields associated with waves, is far too slow.

Diffusive shock acceleration is contained within the Parker cosmic-ray transport equation (see equation (1) of the main article on COSMIC RAYS), if one allows the wind flow to have a compressive discontinuity corresponding to the shock. This compressive discontinuity is the site of the acceleration.

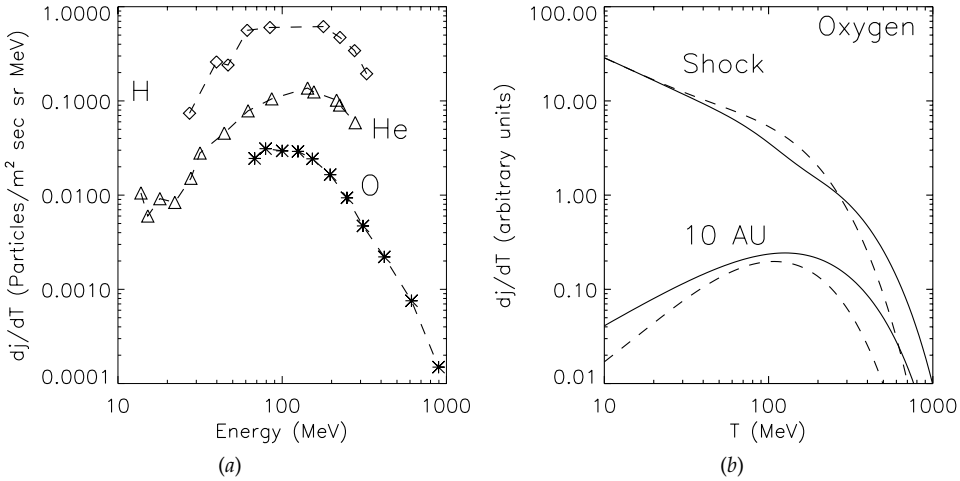

Figure 2. (*a*) Energy spectra of anomalous oxygen, helium and hydrogen observed near 21 AU in 1985 (Cummings and Stone 1987). (*b*) Plot of the computed energy spectra of anomalous oxygen near the heliospheric equator, for two radii, and for the two signs of the heliospheric magnetic field. The full curves correspond to the case where the northern heliospheric magnetic field is directed outward, corresponding to the present sunspot minimum. The broken curves are the same for the 1986 sunspot minimum.

The acceleration process at a quasi-perpendicular shock may be shown to be more closely related to the particle drift in the ambient electric field associated with the motion of the fluid than to the compression of the fluid at the shock, although mathematically it is contained in the compression term of the transport equation. It may be shown that the energy ΔT gained by a particle having electric charge Ze, at a quasi-perpendicular shock, is approximately the electrostatic potential energy $\Delta\phi$ gained in drifting along the shock face: $\Delta T \approx Ze\,\Delta\phi$. We may write for the solar wind

$$(\Delta\phi)_{\max} = B_r r^2 \Omega_\odot / c \approx 240\ \text{MeV}/Z \qquad (1)$$

where c is the speed of light and the numerical value results from using a radial magnetic field of 3.5 γ at a radius of 1 AU and a solar rotational angular velocity $\Omega_\odot = 2.9 \times 10^{-6}$. It follows, then, that for particles having charge Z, there is in general a characteristic energy $T_c \approx Ze(\Delta\phi)_{\max}$ above which the spectrum begins to decrease rapidly. Because of this, any multiply charged particles should be accelerated to higher energies than singly charged ones. Particles will 'drift off' of the shock before gaining more energy. Singly charged particles accelerated at the termination shock would then have an energy spectrum at the termination shock which is roughly a power law and which exhibits a decrease above an energy between 200 and 300 MeV. This behavior is seen in figure 2(*a*). This energy limit will not necessarily produce a sharp cutoff in the energy spectrum because the diffusion will cause some particles to gain more energy and some less.

Multiply charged particles can be produced by further interactions with ambient material. These then could gain much more energy, depending on their charge, and will therefore become dominant at higher energies, beyond the characteristic energy for singly charged particles. Observations in the past few years have observed a transition to multiply charged anomalous cosmic rays at energies greater than some 240 MeV.

Results of model calculations

The scenario discussed above has been incorporated into both two- and three-dimensional numerical simulations of transport and acceleration in the heliosphere, which solve the transport equation for realistic parameters.

We note that the general heliospheric magnetic field (see article on the SOLAR MAGNETIC FIELD) changes sign every 11 yr, during sunspot maximum. The motions of energetic charged particles depend to a significant degree on the sign of the magnetic field. In particular, the drift velocity, given for an isotropic distribution of particles of velocity w and momentum p in an ambient magnetic field $\boldsymbol{B}(\boldsymbol{r})$, is given by the expression

$$\boldsymbol{V}_d = \frac{pcw}{3Ze} \nabla \times \frac{\boldsymbol{B}}{B^2}. \qquad (2)$$

Clearly, $\boldsymbol{V}_d$ reverses direction with the change in sign of the magnetic field. During the current period of sunspot minimum, the northern magnetic field of the Sun is directed outward from the Sun, whereas prior to the last maximum it was directed inward. The present models are most accurate during sunspot minimum, when the interplanetary current sheet is closest to being equatorial, and so we basically discuss two heliospheres, one near a sunspot minimum when the field is outward (current) and one near the next sunspot minimum, when the field is inward.

First consider the model results for the case where low-energy particles are injected uniformly at all latitudes at the shock. The computed and observed spectra are

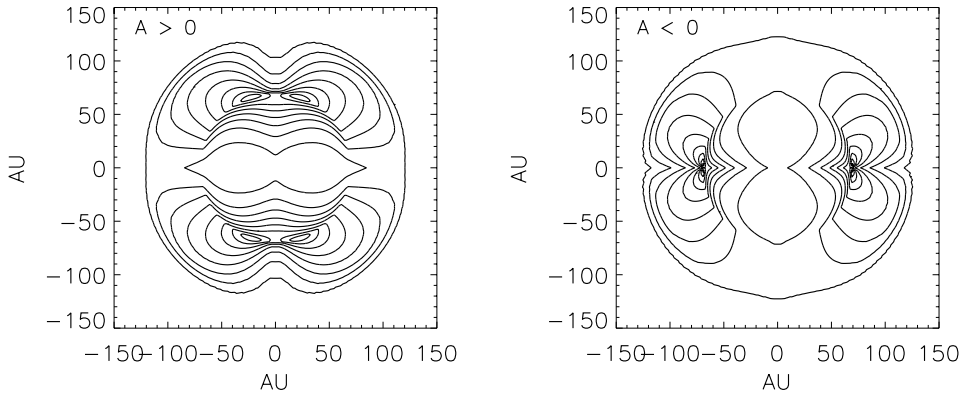

Figure 3. Equal-intensity contours computed for 8 MeV/nucleon anomalous oxygen, as a function of position in a meridional plane, as computed for the model parameters discussed in the text. The left panel is for the present sunspot minimum and the right is for the 1986 minimum.

compared in figure 2, for data taken in 1985 (northern magnetic field inward). The computed energy spectra of anomalous oxygen are clearly in good agreement with the observed spectra. This is also true of other spectra, as well.

Figure 3 illustrates contour plots of the intensity of the modeled anomalous oxygen as a function of heliocentric radius and polar angle, in a solar meridional plane. We see that the intensity increases with radius, much as does that of the galactic cosmic rays, out to the termination shock (at a radius of 60 AU). Beyond, the intensity decreases out to the outer boundary of the heliosphere. Along the shock, the **maximum** intensity occurs at a latitude which shifts as the sign of the magnetic field changes. If the northern interplanetary magnetic field is outward ($A > 0$), the particles drift toward the pole along the shock face and then inward and down from the poles to the current sheet, and the intensity maximum is near the poles. For $A < 0$, the drifts are in the opposite direction, and the maximum shifts to the equator.

There have been numerous measurements of the radial and latitudinal gradients of the anomalous component. It is a general feature of the simulations of anomalous cosmic rays and galactic cosmic rays that, for identical parameters, the latitudinal gradients of the anomalous cosmic rays are significantly larger than those for galactic particles. This is in large part due to the large latitudinal gradient of anomalous cosmic rays induced by drift during the acceleration at the shock. This is also true in the models.

A robust prediction of the models is that the latitudinal gradient near the current sheet, near sunspot minimum, should change sign in alternate sunspot minima. In particular, during the last sunspot minimum, near 1975, the intensity of both galactic cosmic rays and the anomalous component should **increase** away from the current sheet, whereas during the 1986 sunspot minimum the cosmic rays should **decrease** away from the current sheet. Near sunspot minimum, when the current sheet is nearly flat, the effects of these drifts are expected to be the most important. In 1977, PIONEER observed a positive gradient of anomalous helium away from the current sheet, as predicted. Observations carried out during the last sunspot minimum during a period in 1984 and 1985, when the current sheet tilt went below the latitude of the VOYAGER 1 spacecraft, found that the sign of the latitudinal gradient changed from being positive to negative, again as predicted by the theory.

Pickup ions

The above discussion has summarized the present status of the acceleration of anomalous cosmic rays to the highest energies observed, in excess of 1 GeV. Diffusive acceleration at the termination shock of the solar wind seems to be the most likely mechanism for this acceleration.

Not yet fully resolved is the question of how previously unaccelerated pickup ions are accelerated to energies large enough to be further accelerated at the termination shock. This 'injection problem' stems from the fact the the non-accelerated pickup ions have speeds that are less than or equal to the convection speed of the solar wind and hence are not mobile enough to encounter the nearly perpendicular shock the many times necessary to gain significant energy. It has been shown that propagating shocks more readily accelerate low-energy pickup ions than shocks that stand in the solar wind. Consequently, they are more natural injectors of particles and may represent the first stage in a two-step process in accelerating pickup ions to anomalous cosmic-ray energies.

Anomaly

For a particle moving in a conic orbit, the true anomaly is the angle between the point of closest approach to a focus, the focus, and the position of the particle. In the case of a planet moving around the Sun in an elliptical orbit, its true anomaly at any particular instant is the angle between its perihelion position, the Sun (which lies at one focus of the ellipse), and the position of the planet at that instant.

For a body moving around a massive body in an elliptical orbit, the mean anomaly at a particular instant is the angle through which a particle moving at uniform angular speed on a circle of area equal to the ellipse (and with an orbital period equal to that of the real body in its elliptical orbit) will have moved in the time which has elapsed since the real body last passed its closest approach to the massive body. For an ellipse, mean anomaly equals true anomaly at opposite ends of the major axis; for a circular orbit, mean and true anomaly are identical at all times. The concept of mean anomaly is useful in the calculation of the time taken for a body to move along a segment of its orbit.

Antares

The star α Scorpii, said to represent the heart of the scorpion. The name derives from 'rival to Mars', that planet being of similar brightness and color at favorable oppositions. It is a striking red supergiant star, spectral type M1Ib, apparent magnitude 1.06. It is 604 light-years distant (parallax 0.005″), its apparent brightness being due to its great intrinsic luminosity (absolute magnitude −5.3). Antares is a slow, irregular, pulsating variable, its magnitude varying by ±0.14. There is a binary companion of magnitude 5.3 at position angle 274°, separation 2.9″; the binary period is estimated to be of the order of 1000 years.

Antares was known as Satevis by Persian observers *c*. 3000 BC and was one of their four 'Royal Stars'. It marked the autumnal equinox, being prominent during September evenings.

Anthropic Principle

Early humans started with the 'anthropocentric' view that we are located at the center of the universe. Phenomena tended to be interpreted anthropomorphically and even the laws of nature seemed to be human-centered in the sense that they could be exploited for our own purposes. However, this perspective was soon shattered: first by NICOLAUS COPERNICUS' revelation that the Earth moves around the Sun and then by NEWTON's '*Principia*' which led to the 'mechanistic' view of the world (see also COSMOLOGY: A BRIEF HISTORY). Mechanism says that the universe is a giant machine in which the laws of nature operate completely oblivious to the presence of humanity. In the last 40 yr or so, however, there has developed a reaction to mechanism which is called the 'anthropic' view (Barrow and Tipler 1986). This says that, in some respects, the universe has to be the way it is because otherwise it could not produce life and we would not be here speculating about it. Although the term 'anthropic' derives from the Greek word for 'man', it should be stressed that this is really a misnomer since most of the arguments pertain to life in general rather than humans in particular.

To start with a very simple illustration of an anthropic argument, consider the question, why is the universe as big as it is? The mechanistic answer is that, at any particular time, the size of the observable universe is the distance travelled by light since the big bang (see BIG BANG THEORY). Since the universe's present age is about 10^{10} yr, its present size is about 10^{10} light-years. Inherent in this straightforward answer is the belief that there is no compelling reason the universe has the size it does; it just happens to be 10^{10} yr old. There is, however, another answer to this question, one which Robert Dicke first gave (Dicke 1961). His argument runs as follows. In order for life to exist, there must be carbon or at least some form of chemistry. Now carbon is produced by cooking inside stars and this process takes about 10^{10} yr. Only after this time can the star explode as a SUPERNOVA, scattering the newly baked elements throughout space, where they may eventually become part of life-evolving planets. On the other hand, the universe cannot be much older than 10^{10} yr, else all the material would have been processed into stellar remnants such as WHITE DWARFS, NEUTRON STARS and BLACK HOLES. Since all the forms of life we can envisage require the existence of stars, this suggests that life can only exist when the universe is aged about 10^{10} yr.

This startling conclusion turns the mechanistic answer on its head. The very hugeness of the universe which seems at first to point to humanity's insignificance is actually a consequence of its existence. This is not to say that the universe itself could not exist with a different size, only that we could not be aware of it when its size was different. Of course, it could just be a coincidence that the age of the universe happens to be about the time required to produce intelligent life. Also, Freeman Dyson has argued that life could persist well after 10^{10} yr (Dyson 1979). However, this argument does at least give a taste for the type of reasoning the anthropic principle entails. Indeed, the evidence for the anthropic principle rests almost entirely on the large number of numerical 'coincidences' in physics which seem to be prerequisites for the emergence of life and which would otherwise have to be regarded as purely fortuitous.

Scales of structure

Most anthropic arguments involve dimensionless combinations of constants of physics, such as the speed of light (c), Planck's constant ($\hbar$), the gravitational constant (G), the charge of the electron (e) and the masses of elementary particles such as the proton (m_p) and the electron (m_e). For example, the electric 'fine structure' constant, $\alpha = e^2/\hbar c = 1/137$, determines the strength of the electric interaction and plays a crucial role in any situation where electromagnetism is important. Likewise the gravitational fine structure constant, $\alpha_G = Gm_p^2/\hbar c = 6 \times 10^{-39}$, determines the strength of the gravitational interaction and plays an important role in determining the structure of very large objects (such as stars). The fact that α_G is so much smaller than α reflects the fact that the gravitational force between two protons is so much smaller than the electric force between them. Gravity dominates the structure of large bodies only because these tend to be electrically neutral, so that the electric forces cancel out.

What is remarkable is that straightforward physics shows that, to an order of magnitude, α and α_G determine the mass and the size of nearly every naturally occurring object in the universe (Carr and Rees 1979). This is illustrated in figure 1, from which one can read off the scales associated with the universe, galaxies, stars, planets, asteroids, exploding black holes, humans, atoms and protons. Also shown are the Planck scales, the fundamental mass and length units associated with QUANTUM GRAVITY effects. The scales are given in grams and centimeters but also as powers of α and α_G times the proton mass and the size of a hydrogen atom. For example, all stars have a mass of roughly $\alpha_G^{-3/2} \sim 10^{60}$ times the proton mass; the largest planets (such as Jupiter) have a mass which is smaller than this by a factor $\alpha^{3/2}$; and the mass of humans—if we assume that they must live on a planet with a suitable temperature and a life-supporting atmosphere and that they must not shatter whenever they fall down—is of order $(\alpha/\alpha_G)^{3/4}$ times the proton mass. The characteristic mass of a galaxy is less understood but, on one possible argument, can be written as $\alpha_G^{-2}\alpha^4$ times the proton mass. One can express the sizes of these objects similarly. It should be stressed that the dependences on α and α_G in figure 1 are all consequences of straightforward physics. No anthropic argument has been introduced, except—as we shall see shortly—in deriving the scale of the universe itself.

The weak and strong anthropic principles

We now return to Dicke's assertion that the age of the universe (t_0) must be roughly the nuclear-burning time of a star. We can make this argument more specific

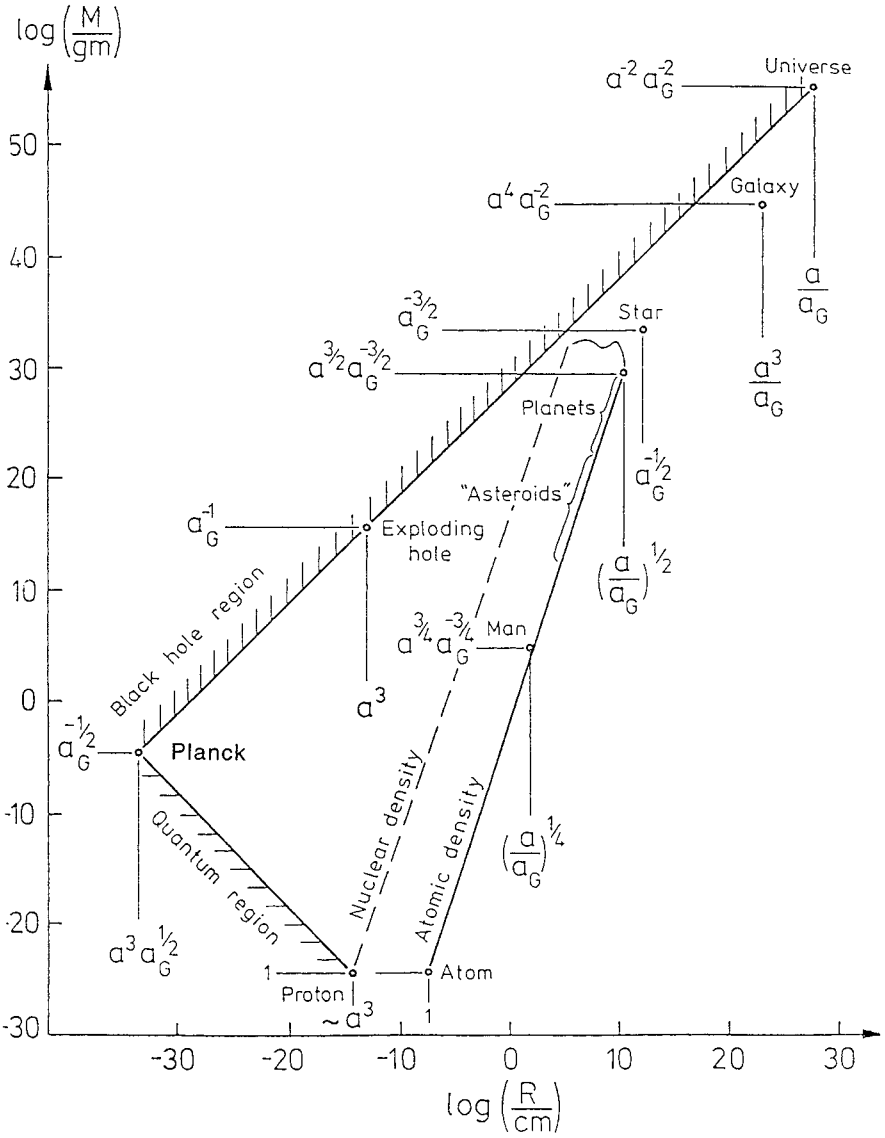

Figure 1. The mass and length scales of various structures in the universe. Also shown are the dependences of these scales on α and α_G in units of the proton mass and the size of a hydrogen atom.

because physics predicts that the lifetime of a star is around $\alpha_G^{-1} \sim 10^{40}$ times the time $t_p = \hbar/m_p c^2 \sim 10^{-23}$ s required for light to traverse the proton. One can infer that the ratio of the size of the universe to the size of an atom must be comparable with the ratio of α to α_G. Thus the anthropic principle explains why these two ratios must have the same huge value of 10^{36}. One can also infer a simple expression for the number of protons in the universe. This is because the big bang model implies that the mass of the observable universe is $\sim \rho_0 c^3 t_0^3$ where ρ_0 is its present density. Since the model also requires $\rho_0 \sim 1/Gt_0^2$, this mass is $c^3 t_0/G \sim \alpha_G^{-2} m_p$, so the number of protons in the universe is of order $\alpha_G^{-2} \sim 10^{80}$. (Note that the number of stars in the observable universe must then be around $\alpha_G^{-1/2} \sim 10^{20}$, a result we invoke later.) The existence of these 'large-number' coincidences has been appreciated for some time but, without resort to the anthropic principle, or alternatively the sort of variable-G model invoked by Dirac (1937), they have to be regarded as fortuitous.

Dicke's argument helps us to understand why the above 'large-number' coincidences prevail but it does not tell us why α_G^{-1} has its particular immense value. His argument is therefore an example of what is termed the weak anthropic principle. This accepts the constants of nature as given and then shows that our existence imposes a selection effect on when we observe the universe. As such it is no more than a logical necessity: saying that

we have to exist at a certain time is no more surprising than saying we have to exist in a certain place (e.g. close to a star). It might be surprising to find what the selection effects are but their existence is not surprising in principle. In fact, most physicists would agree with the weak version of the anthropic principle.

The problem comes when we consider whether the constants of nature such as G are themselves determined by the requirement that life should arise, a notion which is sometimes referred to as the 'strong anthropic principle'. (Rather confusingly, this phrase is also used to describe the rather different notion that the universe *must* have properties such that life can arise (Barrow and Tipler 1986).) That the weak principle may not be the whole story is also suggested by the fact that all the scales shown in figure 1 are relative. If the fine structure constants differed from what we observe them to be, all the scales would change but the basic relationships between them would be the same. For example, one could envisage a hypothetical universe in which all microphysical laws were unchanged, but G was (say) 10^6 times stronger. Planetary and stellar masses ($\sim\alpha_{\rm G}^{-3/2}$) would then be lowered by 10^9 but hydrogen-burning main-sequence stars would still exist, albeit with lifetimes ($\sim\alpha_{\rm G}^{-1}$) of 10^4 yr rather than 10^{10} yr. Moreover, Dicke's argument would still apply: a hypothetical observer looking at the universe when $t_0 \sim t_{\rm MS}$ would find the number of particles in the universe 10^{12} times lower than in ours but they would still find the 'large-number' coincidences described above. If one fixed $\alpha_{\rm G}$ but allowed α to change, the effects would be less extreme, but still very noticeable.

What are the arguments against the 'cognizability' of this kind of small-scale speeded-up universe? One rather loose constraint on $\alpha_{\rm G}$ comes from biological considerations. We have seen that the number of stars in the observable universe is of order $\alpha_{\rm G}^{-1/2}$. If we regard stars—or at least their associated solar systems—as potential sites for life, this is also the number of places where life may have arisen. Of course, this is not a sufficient condition for life because there are a whole set of extra conditions, each of which may be very improbable. For example, we need the star to have a planet, we need the planet to be at a suitable distance from the star, it needs to have a suitable atmosphere and chemistry, and there must be the appropriate conditions for the first self-replicating cells to arise. Clearly therefore the overall probability (P) of life arising at any particular site must be very small. Now if we want to insist that there is life somewhere in the universe, we need the number of sites for life times the probability P to exceed 1. This implies that $\alpha_{\rm G}$ must be less than P^2. For example, if P were 10^{-15}, one would need $\alpha_{\rm G} < 10^{-30}$.

This is not a very precise argument but it does give a qualitative reason why $\alpha_{\rm G}$ needs to be small. There are, however, more specific anthropic arguments that pin down $\alpha_{\rm G}$ more narrowly. The first example of such an argument was given by Brandon Carter and relates to the existence of stars with convective envelopes (Carter 1974). Such a star arises if the heat generated in its core by nuclear reactions is transported to the surface primarily by way of large-scale motions of the stellar material itself. This tends to be the case for small-enough stars (red dwarfs). By contrast, larger stars (blue giants) tend to be 'radiative' in the sense that the heat gets out primarily via the flow of radiation. The dividing line between the two types is some critical mass which can be shown to be around $\alpha_{\rm G}^{-2}\alpha^{10}m_{\rm p}$. This critical mass happens to lie in the mass range $\sim\alpha_{\rm G}^{-3/2}m_{\rm p}$ in which stars actually exist only because of the remarkable coincidence $\alpha_{\rm G} \sim \alpha^{20}$. Were G (and hence $\alpha_{\rm G}$) slightly larger, all stars would be blue giants; were it slightly smaller, all stars would be red dwarfs. The convective condition does not pin down the actual values of α and $\alpha_{\rm G}$ but it does specify a scaling law between them and it explains why $\alpha_{\rm G}$ is so much smaller than α.

Carter ascribed anthropic significance to this relationship on the basis that the formation of planetary systems may be associated with convective stars. This suggestion was based on the observational feature that red dwarfs have much less angular momentum than blue giants and a loss of angular momentum could be a consequence of planet formation. This argument is no longer compelling because there are other ways of losing angular momentum. A better argument might be that only convective stars generate winds in their early phase intense enough to blow away the gaseous envelope of nearby planets, thereby facilitating the formation of solid planets with non-hydrogen atmospheres. In any case, Carter infers that no planets, and hence no life, would form if $\alpha_{\rm G}$ were much larger that α^{20}. If it were much smaller, all stars would be chemically homogeneous owing to convective mixing and one would not get the 'onion-skin' shell structure which characterizes pre-supernova models.

The weak and strong forces

On scales smaller than atoms two more fundamental forces of nature come into play: the strong and the weak force. Like gravity and electromagnetism, the strength of these forces can be described by dimensionless fine structure constants. The weak force has a coupling constant $\alpha_{\rm W} = (gm_{\rm e}^2c/\hbar^3) \sim 10^{-10}$ where $g \sim 10^{-49}$ erg cm^3 is the Fermi constant. Thus its interaction strength is midway between those of gravity and electricity. The dimensionless constant describing the strong force is denoted by $\alpha_{\rm S}$ and has a value of order 10. Although the strong and weak forces are many orders of magnitude stronger than the gravitational force, they are both short range, becoming negligible at distances of 10^{-13} cm and 10^{-15} cm, respectively. For this reason they do not play an important role in determining the structure of objects larger than atoms.

It turns out (Barrow and Tipler 1986) that many features of chemistry are sensitive to the value of $\alpha_{\rm S}$. For example, if $\alpha_{\rm S}$ were increased by 2%, all the protons in the universe would combine at big bang nucleosynthesis into diprotons (nuclei consisting of two protons). In this

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

case, there would be no hydrogen and hence no hydrogen-burning stars. Since stars would then have a much reduced main-sequence time, there might not be time for life to arise. If α_S were increased by 10%, the situation would be even worse because everything would go into nuclei of unlimited size and there would be no interesting chemistry. The lack of chemistry would also apply if α_S was decreased by 5% because all deuterons would then be unbound and one could only have hydrogen.

The most sensitive constraint on the value of α_S is associated with what is called the 'triple-alpha' reaction. The way a star makes carbon is by first combining two alpha particles to make a beryllium nucleus and then adding another alpha particle to form a carbon nucleus ($^4\mathrm{He} + {}^4\mathrm{He} \rightarrow {}^8\mathrm{Be}$, $^8\mathrm{Be} + {}^4\mathrm{He} \rightarrow {}^{12}\mathrm{C}$). The trouble is that beryllium is unstable (otherwise the 'helium flash' in giants would lead to a catastrophic explosion) and it used to be thought that it would decay before the extra alpha particle could combine with it. For many years, therefore, it was difficult to understand why there is any carbon in the universe. Then Fred HOYLE (Hoyle 1953) realized that there must be a resonance (i.e. an enhanced interaction rate) in the second step which allows the carbon to form before the beryllium disappears, i.e. ^{12}C must have a state with energy just above the sum of the energies of ^{8}Be and ^{4}He. There is, however, no similar favourably placed resonance in ^{16}O; otherwise almost all the carbon would be transmuted into oxygen. Once the suggestion was made, the resonance was looked for in the laboratory and rapidly found, so this might be regarded as the first confirmed anthropic prediction. Indeed, the fine tuning required is so precise that Hoyle concluded that the universe has to be a 'put-up job'.

The value of α_W is also involved in an interesting anthropic constraint involving supernovae (Carr and Rees 1979). We have seen that supernovae are essential for life because they spread heavy elements throughout the universe. However, it is still uncertain *why* a star explodes after burning its nuclear fuel. One explanation is that the core of the star becomes very hot when it collapses and this generates a lot of neutrinos which then blow off the envelope as a result of weak interactions. For this model to work, one requires the timescale on which neutrinos interact with nuclei in the envelope to be comparable with the dynamical timescale. If it were much longer, the envelope would be essentially transparent to the neutrinos; if it were much shorter, the neutrinos would be trapped in the core, and could not escape to deposit their momentum in the less tightly bound surrounding layers. The two timescales are comparable provided that $\alpha_G \sim \alpha_W^4$. We know that this relationship holds numerically but the anthropic principle explains why it must hold. So if we accept that α_G is determined anthropically, we must also accept that α_W is so determined.

Rather remarkably the relation $\alpha_G \sim \alpha_W^4$ also plays a crucial role in big bang nucleosynthesis calculations. The prediction that 24% of the mass of the universe is turned into helium when it was just a few minutes old is one of the great triumphs of the big bang picture. However, the helium production depends sensitively on the neutron-to-proton ratio when the weak interactions become slower than the cosmological expansion rate at a temperature of 10^{10} K and the only reason one obtains an interesting helium yield is because the 'freeze-out' temperature is comparable with the neutron–proton mass difference. It turns out that the condition for this is $\alpha_G \sim \alpha_W^4$, precisely the condition required for supernovae. It is not clear to what extent this coincidence can be interpreted anthropically. If α_W were slightly smaller than $\alpha_G^{1/4}$, the entire universe would have burned to helium and the lifetime of a helium star might not be long enough to permit the evolution of life. If α_W were slightly larger than $\alpha_G^{1/4}$, there would have been no helium production at all, although it is not clear that this has any anthropic significance.

Cosmological anthropic constraints

Several more qualitative anthropic constraints derive from cosmological considerations. For example, one can presumably exclude a universe with zero matter density (i.e. pure radiation) since there would then be no baryonic content at all. There are also simple anthropic reasons for why the total density parameter Ω lies within an order of magnitude of 1. (This is the density in units of the critical value which divides models which expand forever from those which recollapse.) If Ω were much larger than 1, the universe would recollapse on a timescale much less than the main-sequence time of a star. On the other hand, if Ω were much smaller than 1, density fluctuations would stop growing before galaxies could bind. This argument requires that Ω be in the range 0.01–100.

It is sometimes claimed that the inflationary scenario requires that Ω equals 1 to much greater precision than this, in which case the anthropic explanation may no longer seem relevant. However, even the inflationary scenario only works if one chooses the vacuum potential so that one has a sufficient number of expansion e-folds and density fluctuations of the right amplitude. The form of this potential may therefore itself be constrained by anthropic arguments. In fact, some theorists now advocate 'open inflationary' scenarios with $\Omega < 1$. In this case, in order to specify the present value of Ω, one needs to invoke what Alex Vilenkin terms the 'mediocrity principle' (the idea that we are most likely to live in a universe with the largest number of galaxies) (Vilenkin 1995). However, this is really just the anthropic principle by another name.

Another important cosmological parameter is the amplitude of the primordial density fluctuations required to explain the currently observed large-scale structure. When these fluctuations came inside the horizon, they must have had an amplitude ε of order 10^{-5}. In this case, galaxies formed when the universe was 10^9 yr old, while clusters of galaxies are separating out at the present epoch. What would happen if the value of ε were different for some reason? If ε were below 10^{-6}, baryons would condense only at very late times when they would be very

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

diffuse. Cooling would then be ineffective, so gas would never condense into stars. On the other hand, if ε were substantially larger than 10^{-3}, baryons would condense early into tightly bound systems that would trap radiation and collapse to supermassive black holes. The evolution in such a universe would be hard to compute but certainly it would contain nothing like galaxies. The anthropically allowed range of ε therefore seems to lie between 10^{-3} and 10^{-6} (Tegmark and Rees 1998).

A third important cosmological parameter is the photon-to-baryon ratio $S \sim 10^9$ (i.e. the ratio of photon density in the microwave background to the average proton density). In the standard big bang model, the background radiation dominated the density of the universe until a time $\sim 10^4$ yr and the formation of galaxies cannot occur until after this. However, for a general value of S this time would be $\sim S^2 \alpha_{\rm G}^{-1/2} t_{\rm p}$ and the age of the universe given by the Dicke argument would then only exceed this for $S < \alpha_{\rm G}^{-1/4}$. Thus we have an upper limit on S of about 10^{10}. A lower limit on S is obtained if one requires that the universe be radiation dominated at cosmological nucleosynthesis, else all the hydrogen would go into helium, and this implies $S > (m_{\rm p}/m_{\rm e})^{4/3} (\alpha_{\rm w}^4/\alpha_{\rm G})^{1/6} \sim 10^4$. Thus anthropic arguments require S to lie in the range 10^4–10^{10}. Of course, in the standard picture the value of S results from a small fractional excess of particles over antiparticles imprinted at around $\sim 10^{-34}$ s after the big bang because of violation of baryon conservation occurring at the grand unified epoch. However, in most GRAND UNIFIED THEORY (GUT) models S is predicted to be of the form α^{-n} where n is an integer, so the anthropic constraint $S < \alpha_{\rm G}^{-1/4}$ merely translates into the constraint $\alpha_{\rm G} < \alpha^{4n}$. If $n = 5$, this just gives the convective star condition (Carr 1991).

Finally we must consider anthropic constraints on the value of the cosmological constant Λ. This is often taken to be zero but this is neither theoretically nor observationally inevitable. The effect of a positive Λ is to cause the universe to embark on exponential expansion when the density of ordinary matter has dropped sufficiently low. The growth of density perturbations is then quenched, so bound systems which have not formed by then never will. For a given value of ε, anthropic considerations therefore set an upper limit to Λ (Efstathiou 1995). Interestingly, this limit is only a factor of 10 higher than value of Λ which some cosmologists favor for our present universe. In the perspective of the 120 powers of 10 uncertainty in the vacuum energy density which particle theorists predict, this is a very severe constraint. Of course, if more precise cosmological observations show that the vacuum energy density is much less than critical density, then one might suspect that Λ is very small, perhaps exactly zero, for some fundamental physical reason.

Interpretations of the anthropic principle

Whether one regards anthropic arguments as coming under the heading of physics or metaphysics depends on how one interprets them. Various sorts of explanation have been suggested and these are illustrated in figure 2. The first possibility is that the anthropic coincidences reflect the existence of a 'beneficent being' who created the universe with the specific intention of producing us (figure 2(*a*)). Such an interpretation is logically possible and may have appeal to theologians, but it is probably unpalatable to most physicists.

Another possibility, proposed by John Wheeler (Wheeler 1977), is that the universe does not properly exist until consciousness has arisen. This is based on the notion that the universe is described by a quantum mechanical wavefunction and that consciousness is required to collapse this wavefunction. Once the universe has evolved consciousness, one might think of it as reflecting back on its big bang origin, thereby forming a closed circuit which brings the world into existence (figure 2(*b*)). Even if consciousness really does collapse the wavefunction (which is far from certain), this explanation would also have to be regarded as metaphysical.

The third possibility is that there is not just one universe but lots of them, all with different randomly distributed coupling constants. In this case, we necessarily reside in one of the small fractions which satisfy the anthropic constraints. With this interpretation, the fact that the constants have the values required for life just becomes an aspect of the weak anthropic principle, for conscious observers need not only be at special points in time and space but also in special universes. Invoking lots of extra universes might seem rather uneconomical but there are several physical contexts in which it makes sense.

One possibility is connected with the 'Many Worlds' interpretation of quantum mechanics originated by Hugh Everett (Everett 1957). The idea here is that the universe splits every time the wavefunction collapses as a result of an observation. This means that the universe is continuously branching into a huge number of parallel worlds and this gives rise to the famous Schrödinger cat paradox. David Deutsch argues that all these worlds are 'real' in some sense (Deutsch 1991). However, they all have the same coupling constants in the Everett picture, so it is a considerable extrapolation to argue that there are also worlds in which the constants differ.

A more plausible context for the 'many universes' scenario arises if the universe is closed. In this case, one could envisage it undergoing cycles of expansion and recollapse, with new values of the coupling constants being generated at every bounce (figure 2(*c*)). During most cycles the constants would not allow life to arise but occasionally the appropriate values would occur and so the universe would become aware of itself. However unlikely the constants are to have the correct values, with an infinite number of cycles it is bound to happen sometimes.

Another 'many universes' scenario arises in the context of the inflationary picture. This proposes that at very early times quantum fluctuations cause tiny regions to undergo an exponential expansion phase (see INFLATION).

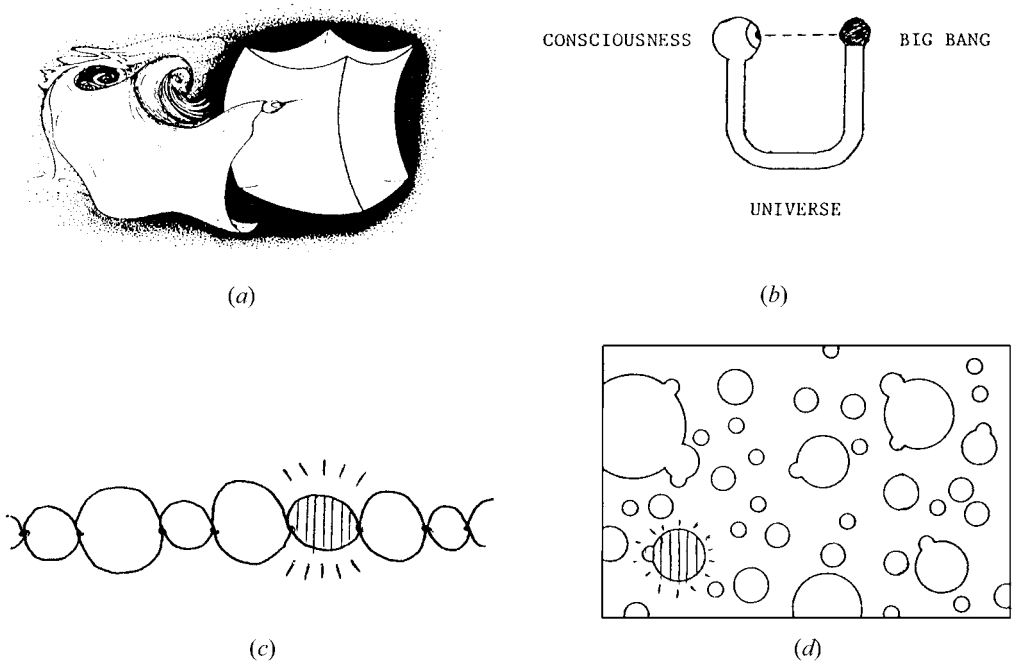

Figure 2. Different interpretations of the anthropic principle. (*a*) God creates the universe; (*b*) consciousness creates the universe; (*c*) cyclic universe; (*d*) inflationary universe.

Each region becomes a 'bubble' and our entire visible universe is then contained within one of these. In principle, as stressed by Andrei Linde (Linde 1985), there could be different values for the coupling constants within each bubble (figure 2(*d*)). In this case, only a small fraction of them would develop consciousness but our universe would necessarily be among that fraction. Both the cyclic and the inflationary models invoke a large—and possibly infinite—number of universes. The only difference is that the first invokes an infinity in time, while the second invokes an infinity in space.

Concluding assessment

The possibility of life as we know it evolving in the universe is contingent on the values of a few basic physical constants—and is in some respects remarkably sensitive to their numerical values. On the other hand, from a physical point of view, the anthropic 'explanation' of the various coincidences in nature can be criticized on a number of grounds. (1) The anthropic arguments are mainly *post hoc*—apart from the triple-alpha resonance, nobody has ever based a successful prediction on the anthropic principle. (2) The anthropic arguments may be unduly anthropocentric in that we have assumed conditions which are specifically associated with human-type life. (3) The anthropic principle does not predict exact values for the constants but only order-of-magnitude relationships between them, so it is not a complete explanation.

The last two objections might be met within the 'many universes' interpretation if one envisages the universes as occupying an abstract multidimensional space of coupling constants (with one dimension for each α). The anthropic principle could then be interpreted as saying that life can only exist in small regions of that space. Lifeforms similar to our own will be possible in some regions; other lifeforms may be possible elsewhere, but life will not be possible everywhere (see also EXOBIOLOGY, LIFE ON OTHER WORLDS). One may not have the same anthropic relation in every life-supporting region of the space but one will have some relation.

The other attraction of the 'many universes' explanation, as we have seen, is that it may be possible to give it a reasonable physical basis (Leslie 1989). Of course, it is not clear that these physical ideas will ever be testable. For example, we will probably never know whether the universe can undergo cycles; even if we can prove that it will recollapse, we cannot be certain that it will bounce into another expansion phase. In the inflation picture the situation is no better because we will never be able to contact the other bubbles. Both pictures are therefore untestable and, in this sense, one might still regard the anthropic principle as being metaphysical.

Perhaps the least radical explanation of the anthropic coincidences is that they may turn out to be a consequence of some unified theory of particle physics. Such theories do, after all, set out to relate the different coupling constants, so it is not inconceivable that they would predict the sort of connections between the different α's discussed above. However, as far as we know, the relationships discussed above are *not* predicted by any unified theory. Even if they were, it would still be remarkable that the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

theory should yield exactly the coincidences required for life.

Finally it should be cautioned that many of the anthropic arguments merely relate to the presence of complexity—the anthropic coincidences could be equally regarded as prerequisites for inanimate objects such as motor cars—so the emphasis on life may be misplaced. In this context, Lee Smolin has conjectured that the constants governing our universe are determined not by anthropic considerations but by a kind of 'natural selection' among universes (Smolin 1992). He postulates that new universes sprout whenever black holes form and that the new constants, while differing slightly from their values in the parent universe, retain some memory of their parentage. This idea is exceedingly speculative and involves physics far beyond anything we can be confident of. However, Smolin's idea at least has the virtue of being testable: it predicts that the properties of our universe should be optimal for black hole formation, so that any tinkering with the constants would reduce the propensity of black holes to form. Conventional astrophysics can at least start to address this question.

Antimatter

Matter composed of elementary particles that have the same masses as their ordinary matter equivalents but which have opposite, or 'mirror image', values of other quantities, such as charge. For example, an anti-electron (or 'positron') has the same mass as an electron but has positive, rather than negative, charge; an anti-proton has the same mass as a proton but has a negative, rather than a positive, charge.

Antiparticles are found naturally among cosmic rays and can be produced in high-energy particle accelerators. Because of the equivalence of mass and energy, high-energy gamma-ray photons can transform into particle–antiparticle pairs (for example, an electron and a positron), the simultaneous production of a particle and an antiparticle being required to satisfy conservation laws, such as the conservation of charge (because a photon has zero charge, it has to transform, for example, into a positive positron and a negative electron, so ensuring that the net charge remains zero). When a particle and its antiparticle collide, they annihilate each other, transforming their mass into energy, normally in the form of gamma-ray photons.

Any antiparticles that are produced in our locality are quickly annihilated through colliding with particles of ordinary matter. While in principle it is possible for antimatter to exist in bulk (for example, stars composed of atoms that consist of anti-protons, anti-neutrons and positrons), and the possibility cannot be excluded, there is no evidence to suggest that this is so. All the bulk matter in our part of the universe is composed of conventional matter, and it is widely believed that the universe itself is dominated by matter rather than antimatter.

Antlia

(the Air Pump; abbrev. Ant, gen. Antliae; area 239 sq. deg.) A southern constellation that lies between Hydra and Vela, and culminates at midnight in late February. It was named Antlia Pneumatica by the French astronomer Nicholas L de Lacaille (1713–62), who charted the southern sky in 1751–2. The IAU adopted the shortened form in 1922.

A small, inconspicuous constellation, overshadowed by its neighbors Centaurus and Vela, the brightest star in Antlia is of magnitude 4.3. Interesting objects include ζ Antliae, a wide double star with pale yellow (A9 and A1) components, magnitudes 5.9 and 6.2, the latter of which is itself double, having a pale yellow (A1) component, magnitude 7.0, separation 8″, S Antliae, an eclipsing binary (range 6.4–6.9, period 0.65 day), and NGC 2997, a tenth-magnitude spiral galaxy.

Apache Point Observatory

The principal projects at Apache Point Observatory at Sunspot, New Mexico, USA, are the 3.5 m telescope, the Sloan Digital Sky Survey and New Mexico State University's 1.0 m telescope. The 3.5 m telescope construction incorporates many innovations: compact and lightweight design, thermal control, multiple instruments and remote observing. The SLOAN DIGITAL SKY SURVEY is generating a three-dimensional map of a large volume of the northern night sky using an array of sensitive instruments coupled to a 2.5 m telescope.

The Observatory is owned by the Astrophysical Research Consortium consisting of the University of Chicago, Institute for Advanced Study, Johns Hopkins University, New Mexico State University, Princeton University, University of Washington and Washington State University. The Sloan Digital Sky Survey is a joint project of the University of Chicago, Fermilab, the Institute for Advanced Study, the Japan Participation Group, the Johns Hopkins University, the Max Planck Institute for Astronomy, Princeton University, the United States Naval Observatory and the University of Washington.

Aperture Synthesis

A technique, also known as Earth-rotation synthesis, that enables the outputs of two or more radio telescopes to be combined to give the same resolution as a single radio dish of aperture equivalent to the maximum separation of the dishes.

A single observation with a conventional radio interferometer produces high resolution only in a direction parallel to the line joining the two antennae, or dishes. If two radio telescopes (A and B) are set up at opposite ends of a track and continue to observe a particular radio source for 12 h then, during that time, the rotation of the Earth will change the orientation of the baseline relative to the source. In particular, if the radio telescopes were located at the north pole, the Earth's rotation would cause A to trace out a semicircle around B, so effectively tracing out a half-ring strip of a 'dish' centered on B. The data received by the dishes are stored and the other half of the ring can be constructed mathematically. Dish A is then moved a little closer to B to enable another 'ring' to be filled in and the process repeated until the entire 'dish' has been synthesized. The mass of accumulated data is then converted into an image of the source equivalent to that which would be obtained by a single dish of aperture equal to the maximum separation of the two dishes. In practice, the resolution achieved along one diameter of the 'dish' (north–south, say) will be the same as that at right angles to this direction (east–west) only if the declination of the source is 90°; resolution along the north–south direction decreases for sources closer to the celestial equator.

A synthesis array with only two dishes would take a very long time to build up the effect of a single large dish. The process may be speeded up by using more than two dishes, some of which may be fixed and others movable and, in some cases, the dishes making up the array can be set out along more than one track. The largest complete Earth-rotation synthesis system is the Very Large Array (VLA), located in the New Mexican desert close to Socorro. The VLA, which comprises 27 dishes, each 25 m in diameter, set out along a Y-shaped track, can simulate a single dish 36 km in diameter. Usually, the outputs from the various dishes are linked together by cables, but the Multi-Element Radio-Linked Interferometer Network (MERLIN), in the UK, uses radio links to connect dishes separated by distances of up to 230 km. Because it links a number of widely separated individual dishes it cannot simulate, and attain the sensitivity of, a complete dish. Nevertheless, it can detect details as small as 0.01 arcsec at its shortest operating wavelengths.

Apex

The direction of motion of the Sun relative to the stars in the local part of the Galaxy is known as the solar apex, or the apex of the Sun's way. Observations of the proper motions of stars indicate that they show a tendency to diverge from a point in the constellation Hercules, and to converge towards a point in the constellation Columba. These observations indicate that the Sun is moving at a velocity of about 19.5 km s^{-1}, towards a point at right ascension (RA) 18 h and declination (dec) $+30^{\circ}$ in Hercules and away from a point at RA 6 h and dec -30° in Columba (the solar antapex).

Apex can also refer to the point on the celestial sphere towards which the Earth appears to be moving as a result of its orbital motion around the Sun.

See also: antapex.

Aphelion

The point in the elliptical orbit of a planet or other object around the Sun at which it is farthest from the Sun. The Earth, for example, reaches aphelion in July, when it is just over 152 million km from the Sun.

Compare: perihelion.

Aphrodite Terra

The largest of the three main upland regions of Venus (the other two being Ishtar Terra and Lada Terra), extending almost halfway around the planet's equator and centered at 5.8 °N, 104.8 °E. Its overall length is 9999 km. It takes its name from the Greek goddess of love. The western end of Aphrodite is formed by two distinct units of elevated terrain: Ovda Regio at the far west, and Thetis Regio to its east, both rising to about 4 km about the planet's mean surface level. At the eastern end lies a similar region, Alta Regio, and beyond it the less elevated Ulfrun Regio. Like Ishtar and Lada Terrae, these regiones in Aphrodite are characterized by the type of terrain termed tesserae—areas of intersecting troughs and ridges. Between Thetis and Alta is a major complex canyon system, the most prominent parts of which are named Diana Chasma and Dali Chasma. These chasmata are steep-sided with rims raised above their surrounds, with a maximum difference, in the case of Dali Chasma, of 6 km between rim and canyon floor. Another, almost circular canyon, Artemis Chasma, lies to the south of Thetis; Ganis Chasma extends northward from Alta. In Alta Regio are situated a number of prominent volcanic peaks, the highest of which, Maat Mons, is over 8 km high. A global analysis of wrinkle ridges—compressive-stress features common on Venus's plains—shows that they tend to be radially aligned on Aphrodite Terra, suggesting a common origin in the event that uplifted Aphrodite.

Apian [Bienewitz or Bennewitz], Peter (1495-1552)

Cartographer, born in Leisnig, Saxony, became professor of mathematics at Ingolstadt, where he founded a press that published maps. He made astronomical instruments, including sundials, quadrants and armillary spheres, and other instruments that would solve spherical trigonometry. His world map is the oldest that uses the name America. His major work (1540), the *Astronomicum Caesareum*, is a sumptuous atlas of the skies with revolving paper models for computation. Apian made clear JOHANN WERNER's proposal for the use of the Moon's position to determine longitude, so that sailors could understand its potential, and thus influenced the establishment of the Royal Observatory at Greenwich, and the Paris Observatory. Observed five comets, including Halley's, and noticed that their tails all pointed away from the Sun.

Apoapsis

The point in an elliptical orbit at which the orbiting body is closest to the body it is orbiting. The prefix 'apo-' or 'ap-' may be attached to various words or roots depending on the body being orbited: for example, apastron for an orbit round a star; apojove for an orbit around Jupiter.

See also: aphelion, apogee.

Apollo

US programme to land men on the moon. Included 11 manned missions, October 1968–December 1972, with three missions restricted to a lunar flyby or orbital survey (Apollos 8, 10 and 13), and six landings (Apollos 11, 12, 14, 15, 16 and 17). Returned 385 kg of lunar soil and rock samples which provided evidence that the Moon was about the same age as the Earth and probably originated from material derived from Earth during a gigantic impact event. Astronauts deployed a wide variety of surface experiments including seismometers, laser reflectors for refining the Earth–Moon distance, heat flow experiments, magnetometers, ion detectors and solar wind spectrometers. Orbital surveys were conducted from the command modules, most notably on Apollos 15–17, which carried mapping and panoramic cameras, and various spectrometers. Data on the distribution of lunar gravity variations were obtained by studies of two subsatellites deployed from Apollos 15 and 16.

Apollonius [Apollonios] of Perga (200–100 BC)

Greek geometer from Perga, now in Turkey, who proposed that the planets revolved around the Sun, and the Sun revolves around the Earth. Apollonius left no astronomical works but is believed to be the inventor of the geometric system of epicycles and eccentric circles, by which perfect circular motions were combined into the actual elliptical orbits of the planets. His work was developed by HIPPARCHUS and PTOLEMY. Apollonius, known as 'The Great Geometer', also wrote a monumental treatise on conic sections entitled *On Conics* in which the terms *parabola*, *ellipse* and *hyperbola* were first used. In a book of optics called *On the Burning Mirror*, he showed that spherical mirrors do not focus parallel rays of light and discussed instead the use of parabolic mirrors.

Apparent Solar Time

Time reckoned by the apparent position of the Sun in the sky. The local apparent solar time (or local apparent time) is defined to be the local hour angle of the Sun (the angle between the observer's meridian and the Sun, measured westwards from the meridian) plus 12 hours. Thus, when the Sun is crossing the meridian at noon, its hour angle is zero, and the local apparent solar time is 0 h + 12 h = 12 hours; when the hour angle of the Sun has increased to 6 hours, the local apparent solar time is 6 h+12 h = 18 h, and so on. Apparent solar time is the time that is displayed on a sundial. Compared to another, regular clock such as a pendulum, it is fast or slow by up to 15 min.

See also: day, hour angle, mean solar time, meridian, sidereal time, Universal Time.

Apparition

The appearance of a celestial body at a time when it is well placed for observation. The term is used especially for objects in the solar system whose orbits are such that they are unobservable for periods of time: for the planets Mercury and Venus, whose morning and evening apparitions occur when they are at greatest elongation (their maximum angular separation from the Sun), and for long-period comets when their orbits bring them into the inner solar system.

Appleton, Edward Victor (1892–1965)

Radiophysicist, born in Bradford, Yorkshire, England, Nobel prizewinner 1947, professor at London, Cambridge and Edinburgh. Discovered the existence of a layer of electrically charged particles about 200 km high in the upper atmosphere (named the *Appleton layer* after him) which, with the Heaviside layer, channels propagating radio waves between distant stations. The layer is affected by the position of the Sun, the sunspot cycle and the solar–terrestrial 'weather'.

Apus

(the Bird of Paradise; abbrev. Aps, gen. Apodis; area 206 sq. deg.) A southern constellation that lies between Triangulum Australis and the south celestial pole, and culminates at midnight in late May. It was first shown on Petrus Planicus's celestial globe of *c*. 1598 as Apis Indica (the Indian Bird), though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, the brightest stars in Apus are α Apodis, magnitude 3.8, and β apodis, magnitude 3.9. There are no other stars brighter than fourth magnitude. Interesting objects include δ Apodis, a wide double star with red (M5) and orange (K3) components, magnitudes 4.7 and 5.3, separation 103″, and NGC 6101, a ninth-magnitude globular cluster.

Aquarius

(the Water-bearer; abbrev. Aqr, gen. Aquarii; area 980 sq. deg.) A southern zodiacal constellation that lies between Pegasus and Piscis Austrinus, and culminates at midnight in late August. Its origin dates back to Babylonian times and it is said to represent Ganymede in Greek mythology, who was snatched up by Aquila (the eagle) on Zeus's behest, to become cup-bearer to the gods. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest* and he included α Piscis Austrini (Fomalhaut) in the constellation.

A large but rather inconspicuous constellation, the brightest stars in Aquarius are α Aquarii (Sadalmelik) and β Aquarii (Sadalsuud), both magnitude 2.9. All other stars are of the third magnitude or fainter. Interesting stars in Aquarius include several doubles, notably ζ Aquarii, a close binary with yellow (F3 and F6) components, magnitudes 4.4. and 4.6, separation 2″, period 856 years, and the Mira-type variable R Aquarii (range 5.8–12.4, period about 387 days). Other interesting objects include M2 (NGC 7089), a seventh-magnitude globular cluster, and two planetary nebulae, NGC 7293 (the Helix Nebula), also seventh magnitude and one of the closest planetary nebulae, with an apparent size of 12.8′, and NGC 7009 (the Saturn Nebula), which is eighth magnitude.

Three major meteor showers appear to radiate from the constellation: the Eta Aquarids, Delta Aquarids and Iota Aquarids.

Aquila

(the Eagle; abbrev. Aql, gen. Aquilae; area 652 sq. deg.) An equatorial constellation that lies between Sagitta and Sagittarius, and culminates at midnight in mid-July. Its origin dates back to Babylonian times and it is said to represent the eagle of Zeus in Greek mythology, which carried the thunderbolts that Zeus hurled at his enemies and which snatched up Ganymede to become cup-bearer to the gods. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest* and he placed the southern ones in the now obsolete constellation of Antinous.

The brightest star in Aquila, α Aquilae (Altair), magnitude 0.8, is one of the stars that, together with α Lyrae (Vega) and α Cygni (Deneb), makes up the asterism of the Summer Triangle. Two fainter stars, γ Aquilae (Tarazed), magnitude 2.7, and β Aquilae (Alshain), magnitude 3.7, lie about 2° north-west and 2.5° south-east respectively of Altair, and together with it form an unmistakable configuration. There are seven other stars of magnitude 4.0 or brighter, including η Aquilae, one of the brightest Cepheid variables (range 3.5–4.4, period 7.18 days). Another bright variable is the Mira-type star R Aquilae (range 5.5–12.0, period about 284 days). The constellation also contains Van Biesbroeck's star, an eighteenth-magnitude red dwarf which, with an absolute magnitude of 19.3, is one of the intrinsically faintest stars known.

The Milky Way passes through Aquila and the constellation contains a number of star clusters and planetary nebulae, the brightest of which is NGC 6709, an open cluster of about 40 stars fainter than ninth magnitude.

Ara

(the Altar; abbrev. Ara, gen. Arae; area 237 sq. deg.) A southern constellation that lies between Scorpius and Apus, and culminates at midnight in early June. It is said to represent the altar upon which in Greek mythology the gods swore allegiance before their battle against the Titans, and that upon which Chiron, the centaur, is about to sacrifice Lupus, the wolf (which was a neighboring constellation before the introduction of Norma in the mid-eighteenth century). Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small, rather inconspicuous constellation, the brightest stars in Ara are α and β Arae, both magnitude 2.8. There are five other stars brighter than fourth magnitude. The Milky Way passes through Ara and the constellation contains a number of star clusters, including NGC 6193, a fifth-magnitude open cluster, and NGC 6397, one of the closest globular clusters, which is just visible to the unaided eye as a faint misty patch.

Arago, Dominique François Jean (1786–1853)

Scientist and statesman, born in Estagel, France. Director of the Paris Observatory, where he invited URBAIN LE VERRIER to determine why Uranus was deviating from its predicted orbit, a study which led to the discovery of Neptune. His scientific achievements were mainly in the fields of astronomy, magnetism and optics. He showed that the light changes polarization when passing through quartz and performed experiments that failed to detect the motion of the Earth with respect to the ether. He took part in the July Revolution (1830), and in 1848 was a member of the provisional government, and was effectively the Head of State for 46 days (perhaps only the second astronomer who has had this distinction, counting ALFONSO X as the first). Working with JEAN-BAPTISTE BIOT, Arago defined the meridian of Paris, used by French sailors until supplanted by the 'prime' meridian of Greenwich in 1884. He made measurements along it of the circumference of the Earth as a preliminary to the determination of the meter, in order to standardize the unit of length. A 'virtual monument' to Arago by the Dutch sculptor Jan Dibbets runs through Paris in the form of 135 brass circles engraved with his name and located along the meridian line.

Aratus [Aratos] (*c*. 315–*c*. 245 BC)

Greek poet and naturalist, author of *The Phenomena*, an account of the constellations and their positions, and of weather signs in heavenly bodies and other natural phenomena. It is based on work by the astronomer EUDOXUS and on a lost treatise of the fourth century BC, perhaps by Theophrastus. Aratus' work is the earliest surviving account of the constellations still in use at the present day.

Arcetri Astrophysical Observatory

The Arcetri Astrophysical Observatory, a government research institute founded in 1972, is located close to the villa where Galileo spent the last 11 years of his life. Under the directorship of Giorgio Abetti (1921–53) it became the growth point of Italian astrophysics with emphasis on solar physics; a tradition continued by his successor Guglielmo Righini (1953–78). Since 1978 the activities have also included: interstellar medium and star formation, extragalatic and high-energy astrophysics, astrophysical techniques and large telescopes.

The Observatory collaborates with the National Research Council in the operation of the 0.5 m Infrared Telescope on the Gornergrat (Swiss Alps) and is the Italian focal point in the collaboration between institutions in Germany, Italy and the United States for the construction of a 2×8.4 m binocular telescope on Mount Graham (Arizona).

Arcetri's staff includes about 45 tenured astronomers and a large number of visiting scientists.

Archimedes of Syracuse (287–212 BC)

Greek scientists and mathematician, born in Syracuse. Remembered for *Archimedes' screw*, used for raising water, and his cry of *eureka* ('I have found it') when he discovered, according to legend while in the bath, the principle of the hydrostatic upthrust on a floating body (*Archimedes' principle*). Discovered formulae for the areas and volumes of spheres, cylinders and a variety of figures. Most of his original astronomical work is lost. In a curious book he attempted to calculate an upper limit to the number of grains of sand which would fill the universe. He was killed, ridiculously, at the siege of Syracuse by a Roman soldier whose challenge he ignored while immersed in a mathematical problem drawn in the sand.

Arcturus

The star α Boötis, a golden yellow giant star (spectral type K2IIIp), with an apparent magnitude of -0.05 it is the fourth brightest star in the sky. Its distance is currently 37 light-years (parallax $0.089''$), but it has been calculated that its high velocity through space will carry it past the solar system in a few thousand years. It will be a spectacular visitor, being about 21 times the Sun's diameter and 98 times its luminosity, having an absolute magnitude of -0.3.

Arecibo Observatory

Located in the limestone hills of northwestern Puerto Rico, Arecibo Observatory is operated by the National Astronomy and Ionosphere Center, managed by Cornell University for the National Science Foundation.

Conceived by William E Gordon, a professor of electrical engineering at Cornell University, the radio-radar telescope was completed in 1963. With its 305 m (1000 ft) diameter dish, which was built into a hillside, Arecibo has the largest collecting area (8 hectares or 18 acres) of any radio antenna in the world.

The Arecibo system operates at frequencies between 50 MHz and 10 GHz (wavelengths between 6 m and 3 cm). With the aid of highly sensitive receivers which are cooled to about 20 K it is able to study extremely weak radio-emitting objects.

Arecibo's spherical reflector requires a 29 m (96 ft) line feed to collect the partially focused radiation. A Gregorian feed system, which uses two mirrors to focus radio waves to a point, was installed in 1997. At the same time, a ground screen and powerful new radar transmitter were installed.

A number of major discoveries have been made with the telescope. They include the first discovery of planets around a pulsar (B1257+12); the first discovery of a pulsar in a binary system; and the discovery of millisecond pulsars. During the 1980s it was used to map the distribution of galaxies in the universe.

Since the first radar transmitter was installed in 1974, Arecibo has been used for solar system exploration, including detailed mapping of the surfaces of the Moon, Venus and a handful of near-Earth asteroids. In the 1960s it enabled astronomers to determine the rotational period of Mercury, and more recently it has been used to search for ice in polar craters on both Mercury and the Moon. The Arecibo radar is also the world's most sensitive instrument for detecting meteors.

During the dedication of a major upgrade to the telescope on 16 November 1974, Arecibo sent the first radio message to extraterrestrials. The transmission contained representations of the fundamental chemicals of life, the formula for DNA, a crude diagram of our solar system and simple pictures of a human being and the Arecibo telescope.

The telescope is still used for SETI research today. One project, known as Phoenix, aims the telescope at specific stars. Another, called Serendip, collects data on certain likely frequencies during all the telescope's other operations, and distributes the data to thousands of volunteers for processing on personal computers.

Argelander, Friedrich Wilhelm August (1799–1875)

Astronomer, born in Memel, East Prussia. Director of the Bonn Observatory, where he organized a survey of the position of all 324 198 stars of the northern hemisphere above the ninth magnitude, published as the star charts and catalogs of the *Bonner Durchmusterung* (BD). His assistant, Eduard Schönfeld (1828–91), made the extension (BDE) into the southern sky. It is staggering to think about this pre-information technology project to observe half a million stars twice each by eye, their brightnesses and positions calculated, charted and printed by hand.

Argo Navis

(the Ship) a large southern constellation representing the ship *Argo* of Jason and the Argonauts in Greek mythology whose brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*. It was divided up by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, into the constellations Carina (the Keel), Vela (the Sails), Puppis (the Poop or Stern) and Pyxis (the Compass), the stars of which all share a single series of Bayer letters. The brightest star of Argo Navis is now α Carinae (Canopus or Suhel), magnitude -1.9.

Ariel

A mid-sized satellite of Uranus, discovered by William Lassell in 1851. Its diameter is 1160 km and it orbits at a distance of 191 000 km. Of Uranus's five mid-sized satellites, Ariel has the brightest surface, and has been the most geologically active (Miranda excepted). An older cratered surface is criss-crossed by spectacular deep, steep-sided canyons whose broad floors themselves show signs of further activity, with volcanic flooding and sinuous, winding troughs reminiscent of the Moon's sinuous rilles. (Such low-temperature 'cryovolcanism' is possible because a water–ammonia eutectic mixture can behave as a viscous lava.) The longest of these canyons is the 622 km long system known as Kachina Chasmata. Such activity must have been caused by tidal heating. At present Ariel lacks any orbital resonance with neighboring satellites that could cause tidal heating, but this may have been different in the past. When the molten icy interior eventually solidified, it would have expanded, splitting the crust to form the canyons.

Ariel

Series of six UK-led scientific satellites launched 1962–79. The first four studied the ionosphere, while the last two were x-ray astronomy satellites. Ariel 3 was the first all-British satellite. The UK–US Ariel 5, launched in October 1974, operated for more than five years and discovered dozens of new x-ray sources, including a number of transient sources such as Cygnus X-1. Ariel 6 suffered technical problems and produced few results.

Aries

(the Ram; abbrev. Ari, gen. Arietis; area 441 sq. deg.) A northern zodiacal constellation that lies between Taurus and Pisces, and culminates at midnight in late October. It represents the ram in Greek mythology whose golden fleece was the quest of Jason and the Argonauts. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*. In Ptolemy's day the Sun was in Aries at the vernal (spring) equinox and although as a result of precession this position now lies in the neighboring constellation of Pisces, it is still sometimes called the first point of Aries.

A rather inconspicuous constellation, the brightest stars in Aries are α Arietis (Hamal), magnitude 2.0, and β (Sheratan), magnitude 2.6. γ Arietis (Mesarthim) is a fine visual binary with white (B9) and pale yellow (A1) components, both of magnitude 4.6, separation $8''$. It was one of the first double stars to be discovered, being found serendipitously by the English physicist Robert Hooke (1635–1703) while observing the comet of 1664. α, β and γ Arietis form a narrow triangle, which is the most easily recognized part of the constellation.

Variable stars in Aries include the Mira-type stars U Arietis (range 7.2–15.2, period about 371 days) and R Arietis (range 7.4–13.7, period about 187 days). The brightest galaxy is NGC 772, a tenth-magnitude spiral.

Aristarchus of Samos (310–230 BC)

Greek philosopher, born on the island of Samos. According to ARCHIMEDES, Aristarchus hypothesized that the fixed stars are stationary, and that the Earth orbits the Sun, which is at the center of the universe. Since the stars did not show motions that reflected the motion of the Earth, the stars must be at great distances. The Babylonian astronomer SELEUCUS was the only astronomer who took up this concept until COPERNICUS in 1543, who knew something of Aristarchus' theory (*see* THOMAS KUHN). Aristarchus also used geometric methods to measure the size of the Sun, Moon and Earth. His methods were correct in principle and inaccurate only by an unprecedentedly small one order of magnitude, due to failures in the instruments and assumptions rather than the reasoning. According to Plutarch, Aristarchus's contemporaries rejected 'with abhorrence the view of those who have brought to rest the things which move and set in motion the things which by their nature and position are unmoved, such a supposition being contrary to the hypotheses of mathematics'.

Aristotle of Stagira (384–322 BC)

Aristotle was a Greek philosopher and scientist, born in Stagira. Aristotle's lectures were compiled into 150 volumes, including *Physics*, *Metaphysics* and *De Caelo et Mundo* (*On the Heavens and Earth*), in which he accepted the heavenly spheres of EUDOXUS, thought the Earth to be spherical and imagined a perfectly spherical, unchanging universe of spheres centred on the Earth and carrying the planets. Aristotle followed Eudoxus in suggesting that there were four elements: earth (solid), fire (energy), water (liquid) and air (gas). Each element could be hot, wet, dry or cold. Aristotle added a fifth element called ether, which he believed to be the main constituent of the celestial bodies. This divine element, he believed, is uncompounded, ungenerated, eternal, unalterable and neither heavy nor light. It can be found in its purest form in the celestial regions, but becomes adulterated in the area below the Moon. Aristotle's view of the universe was hierarchical, and he made a sharp distinction between the eternal and immutable heavens and the sublunar, imperfect world of change (hence the subsidiary meaning of the word 'sublunary'). The motion of celestial objects was therefore always natural, circular and continuous. In medieval times, Aristotle's cosmology was codified and systematized to become the dominant world view (see MEDIEVAL COSMOLOGY).

Armagh Observatory

The Armagh Observatory is a modern astronomical research institute with a rich heritage. Founded in 1790 by Archbishop Richard Robinson, its mission is to advance the knowledge and understanding of astronomy and related sciences. Around 20 astronomers carry out multi-disciplinary research on problems concerning the Sun and other stars, star formation, comets and asteroids, extra-solar planetary systems and solar system–terrestrial relationships.

The Observatory is supported by the Department of Education Northern Ireland and the UK PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL. It is situated close to the center of the city of Armagh in Northern Ireland in grounds that include the Armagh Planetarium and the Armagh Astropark.

For further information see http://www.arm.ac.uk/.

Armillary Sphere

A device of ancient origin that was used to measure or describe celestial positions. In essence, it is a model of the celestial sphere consisting of a set of rings, each of which represents a great circle such as the celestial equator or ecliptic, that revolves within a framework of fixed circles that represent, for example, the observer's horizon and meridian. When used for observation, it included a pivoted ring on which open sights were mounted, the position of the object of interest being read off from graduated scales on the various rings.

Armillary spheres were used for positional measurements in ancient and medieval times by observers such as Hipparchus, Ptolemy and Tycho Brahe and were widely used from the Middle Ages onwards for the teaching of astronomy.

Armstrong, Neil Alden (1930–)

Astronaut, born in Auglaize County, OH, trained as a pilot (Korean War). He flew on Gemini 8 and in 1969, with Michael Collins and EDWIN ALDRIN, took Apollo 11 to the Moon. On 21 July 1969, at 02:56 GMT, Armstrong became the first man to walk on the Moon, with the famous statement, 'That's one small step for a man, one giant leap for mankind'.

Arrhenius, Svante August (1859–1927)

Swedish chemist, Nobel prizewinner (1903). In *Worlds in the Making* (1908), he suggested that life on Earth had begun when space-traveling spores reached Earth on a meteorite—the panspermia hypothesis.

Art and Literature

The mind-expanding properties of astronomy affect writers and artists as much as (or possibly more than) people in general, and there is a long tradition of the use of astronomical references in literature and art.

Astronomy and art

Among the intents of fine art (painting, sculpture and objects which are made to be admired, rather than to be useful) is to comment by metaphor or analogy on human activities. Such activities may be set against or associated with astronomical phenomena, either for their own interest or as a comment.

In paintings of the crucifixion, for example, are often shown images of eclipses. These are literal representations of the sudden darkness that the scriptures say occurred at the death of Jesus. They are also metaphors for the extinguishing of an important person, and examples of the 'pathetic fallacy' in which the natural world is identified as reacting to the human activities which happen in it.

Likewise, the Florentine painter Giotto de Bondonel was commissioned in 1303 to decorate the interior of a chapel belonging to a wealthy Paduan merchant, Enrico Scrovegni, and he painted 38 religious scenes, one of which was *The Adoration of the Magi* (see also http://www.mystudios.com/gallery/giotto/17a.html). The worship of the infant Jesus in a stable was set under the Star of Bethlehem, a symbol of change and a portentous celestial mark of the birth. Giotto depicted it as a blazing comet. He was inspired by Halley's Comet, which had returned to perihelion in 1301 and which the painter had undoubtedly seen. It was fitting that the spacecraft sent into the nucleus of Halley's Comet during the return of 1986 should have been named GIOTTO.

On a more individual level, Vincent van Gogh painted *Starry Night* (1889, Museum of Modern Art, New York City; see also http://sunsite.org.uk/cgfa/gogh/gogh3.htm). It shows a Provençal village with a church and houses with lit windows in a landscape of hills, olive and cypress trees, shown at night below a starry sky, with crescent moon and swirling Milky Way. It appears that the skyscape is a free rendering of the night sky at the time of its painting. Whatever its natural realism, the cosmic background of dizzying lights, overarching the human landscape below, represents a disturbing cosmic background to the smaller human events below, including, one must suppose, Vincent's developing madness, culminating in his suicide the following year.

The same Milky Way runs across the night sky in Albrecht Altdorfer's *Flight into Egypt* (1609, in the Pinakothek at Munich). Again, it is a cosmic background to the events, shown small, that are taking place on Earth below as the Holy Family travels on donkey, fleeing from the massacre of the infants by Herod. Altdorfer's is the first representation of the Milky Way as a mass of individual stars.

Astronomical instruments are often shown in portraits. They are interesting decorations that reflect the interests, attainments and education of the sitter(s) and may or may not be directly associated with the subject. *The Ambassadors* (1533, National Gallery, London; see http://www.nationalgallery.org.uk/collection/w_wing/index.html) is a full-length portrait of two wealthy, educated and powerful young men, Jean de Dinteville, the French Ambassador to England, and Georges de Selve, Bishop of Lavaur. The artist, Hans Holbein the Younger (1497/8–1543), has depicted the two men standing either side of a table bearing a collection of globes, books and astronomical and musical instruments. A sundial on the table is identical to that featured in Holbein's portrait of the astronomer *Nicholas Kratzer* of 1528 (Musée du Louvre, Paris; see http://www.louvre.fr img/photos/collec/peint/grande/inc1343.jpg). The plausible guess is that the sundial was designed or made by Kratzer, and its image was re-used and incorporated by Holbein into *The Ambassadors* as flattery.

Astronomical references in the illustrated books of the English romantic poet William Blake are not favorable to science. *God as an Architect*, an illustration from *The Ancient of Days*, depicts God as an old man, kneeling on stormy clouds against a fiery sun, coldly measuring the cosmos with dividers (see http://sunsite.org.uk/cgfa/blake/index.html). Blake depicted *Newton* (see http://www.cube.icestorm.net/peirson/phil/blake/blake2.html) as a misguided Greek-god-like hero whose gaze was directed only downwards at sterile geometrical diagrams that he also measures with dividers. It is curious that this scornful depiction of Newton is often seen displayed as a poster on the walls of university physics departments.

By contrast to Blake's pessimism, his contemporary and countryman, Samuel Palmer, shows bucolic scenes in an idealized England (e.g. worshippers *Coming from Evening Church*, 1830, *A Hilly Scene* circa 1826–1828, Tate Gallery, London; see http://www.tate.org.uk/coll/cchtm/n03697_c.htm and http://www.tate.org.uk/coll/cchtm/n05805_c.htm) under a benign, evening sky with glowing moons, and the planet Venus.

Astronomy and literature

Just as artists have used astronomical themes as a backdrop to human affairs, so too have writers. Astronomical references abound in the writings of William Shakespeare (1564–1616). His plays contain numerous speeches for and against astrology, views against being expressed mostly by the more pushy, rebellious characters. Shakespeare was born after Copernicus published his theory of the solar system in 1543 and was a contemporary of enthusiastic English

and Institute of Physics Publishing 2001

proponents of the new view of the Universe, such as THOMAS DIGGES (died 1595), WILLIAM GILBERT (1540–1603) and JOHN DEE (1527–1608). Nevertheless, no trace of this controversy is found in Shakespeare's works, save in disputes about the validity of astrology.

Thomas Hardy (1840–1928) was a poet and prolific novelist of the Wessex countryside. He described his novel *Two on a Tower* as a 'slightly-built romance' that 'was the outcome of a wish to set the emotional history of two infinitesimal lives against the stupendous background of the stellar universe, and to impart to readers the sentiment that of these contrasting magnitudes the smaller might be the greater to them as men' (preface of edition of 1895). Peter Ackroyd (1949–), an English novelist, known for his handling of the relativity of time in his work, also set his novel *First Light* in a west-country landscape which shows a palimpsest of time in its tumuli, folk memories and modern observatory.

It is possible in literature to make explicit comment on quite abstract astronomical ideas. The size of the universe is one of astronomy's imaginative pulls, and the very word 'astronomical' has gathered a subsidiary meaning of 'immense' because the quantities in astronomy involved are so vast. Sometimes the reaction to the distances of stars is awe and fear, as in *Pensées* by Blaise Pascal (1623–1962):

> The eternal silence of those infinite spaces strikes me with terror.

Because of the long times for the travel of light from a star to us, the image of the sky that we perceive at this moment originated long ago and may show the memory of a star that has since reached the end of its life and no longer exists. The *Ode to Charles Sumner* by Henry Longfellow (1807–1882) (1979 *Complete Works* (Oxford: Oxford University Press) p 326) illustrates this idea:

> Were a star quenched on high,
> For ages would its light,
> Still travelling downward from the sky,
> Shine on our mortal sight.
>
> So when a great man dies,
> For years beyond our ken
> The light he leaves behind him lies
> Upon the paths of man.

American poet Robert Frost (1874–1963) had a lifetime interest in astronomy, which started from the age of 15 when he installed in the upper room of his parents' house a small telescope, bought with money from selling magazine subscriptions. In a speech two months before his death, he gave his philosophical reaction to astronomy: 'How stirring it is, the Sun and everything. Take a telescope and look as far as you will. How much of the universe was wasted just to produce puny us. It's wonderful … fine'. In *A Star in a Stone Boat* (Frost R 1962 (Harmondsworth: Penguin) p 116) he described how celestial material was part of the fabric of the Earth and its contents.

> Never tell me that not one star of all
> That slip from heaven at night and softly fall
> Has been picked up with stones to build a wall.

Primo Levi (1919–1987) was an Italian Jewish poet and writer. Trained as an industrial chemist, he had a dramatic life as a Piedmont partisan, and was a witness, participant and survivor from the concentration camp at Auschwitz. He committed suicide, apparently in despair at the human condition. His poetry *In the Beginning* from 1998 *Collected Poems: Shema* transl R Feldman and B Swann (London: Faber and Faber) p 27) describes the same thought as Frost, in relation to the big bang:

> From that one spasm everything was born:
> The same abyss that enfolds and challenges us,
> The same time that spawns and defeats us,
> Everything anyone has ever thought,
> The eyes of a woman we have loved,
> Suns by the thousands
> And this hand that writes.

However again, just as in fine art, not all references in literature to astronomy are favorable, and Newton is in the firing line. At a drunken dinner on 28 December 1817, attended by four literati—Benjamin Haydon, William Wordsworth, Charles Lamb and John Keats—Lamb abused Haydon for putting a bust of mathematical scientist Isaac Newton into a picture that he had just painted. Lamb derided Newton as 'a fellow who believed in nothing unless it was as clear as three sides of a triangle'. Lamb proposed a toast to 'Newton's health and confusion to mathematics'. Keats agreed, and, with Wordsworth, lamented the destruction of beauty by science. This derision of science appears in Keats' and Wordsworth's poetry. No scientist would agree with the sentiment expressed by Keats (*Lamia Part II* lines 229–38 in Garrod H W (ed) 1956 *The Poetical Works of John Keats* (Oxford: University Press) p 176):

> Do not all charms fly
> At the mere touch of cold philosophy?
> There was an awful rainbow once in heaven:
> We know her woof, her texture; she is given
> In the dull catalogue of common things.
> Philosophy will clip an Angel's wings,
> Conquer all mysteries by rule and line,
> Empty the haunted air, and gnomed mine—
> Unweave a rainbow…

Science fiction

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001

Astronomy is associated with a distinct literary genre, namely science fiction. 'Science fiction is that class of prose narrative treating of a situation that could not arise in the world we know, but which is hypothesised on the basis of some innovation in science or technology, or pseudo-technology, whether human or extra-terrestrial in origin' (Amis 1960).

Science fiction has a long and honorable history. It goes back to the 2nd century AD, since the first true novel about an expedition to the Moon was written at that time by a Greek satirist, Lucian of Samosata. He called it the *True History*, because it was made up of nothing but lies from beginning to end. It describes things that he had 'neither seen nor suffered nor learned from another, things which are not and never could have been; therefore my readers should by no means believe them'. Lucian combined a cool brain with a gift for fluent, easy writing, and he possessed a strong sense of humor.

His travelers are sailors, who were caught up in a water spout as they passed through the Pillars of Hercules (our Straits of Gibraltar), and were hurled upward so violently that after seven days and seven nights they landed on the Moon. They were arrested by lunar warriors and imprisoned by the King of the Moon. Associating the Aristotelian perception of celestial bodies as more perfect than the Earth with the Moon, Lucian described the Moon-men as far more advanced than the people of Earth were. Anything unclean or impure was abhorrent to them. Sex was either unknown or ignored, and when a Moon-man died he merely dissolved into smoke, so that no remains should be left for burial. This convention that celestial beings are more pure than we are survives to this day in beliefs about extraterrestrial visitors in UFOs.

Johann KEPLER's *Somnium (Dream)* was very different. In 1593, as a 22 yr old student at the University of Tübingen, Kepler wrote a dissertation, from a Copernican standpoint, on how the heavens would appear to an observer on the surface of the Moon. Debate on this radical thesis was suppressed. *Somnium*, written by 1609 and published in 1634, expands the thesis into a work of imagination. It was, and was meant to be, educational as well as entertaining. There were 223 notes explaining its references. In its emphasis on what to Kepler was science rather than on the adventure story, the work was the first science fiction story (hard core, in which the science is the most important feature, as opposed to science fantasy). Kepler's hero, an Icelander named Duracotus, is carried to the Moon by a demon. Kepler knew that the Earth's atmosphere does not extend all the way to the Moon, and that there must be a neutral point where the gravitational pulls of the Earth and Moon balance. Kepler also knew that the Moon always keeps the same face turned toward the Earth, and explains that conditions on the two hemispheres are quite different. He describes a lunar eclipse as seen from the Moon (i.e. an eclipse of the Sun by the Earth) and what a solar eclipse looks like to a moon-dweller (i.e. the transit of the umbral shadow across the face of the Earth).

Jules Verne's *From the Earth to the Moon* appeared in 1865 and was followed later by the sequel, *Round the Moon*. Verne made a conscious effort to keep to the facts as he knew them, and on the whole he succeeded remarkably well, even though his basic method of travel was wrong. His travelers were fired to the Moon from the barrel of a huge cannon, and set off at a speed of 7 miles^{-1}. Numerically Verne was correct; 7 miles s^{-1} is the Earth's escape velocity, and a projectile launched at this speed would never return. Unfortunately, the projectile would at once be destroyed by friction against the atmosphere, and in any case the shock of departure would certainly reduce any travelers to jelly, but at least Verne made it all sound plausible. His description of the Moon was based on the best information available, and his plot is ingenious; the projectile encounters a minor satellite of the Earth, and its path is changed so that instead of reaching the Moon the travelers are boomeranged back to the Earth.

H G Wells' *The War of the Worlds* (1898) describes how Earth is invaded by grotesque monsters from Mars, fleeing the desiccation of their planet. They cause devastation until they are destroyed by terrestrial bacteria, against which they have no immunity. In 1938 a radio broadcast of the novel, produced by Orson Welles, caused widespread panic in parts of the USA, listeners mistaking it for a real news bulletin.

A novel of very different kind was written by KONSTANTIN EDUARDOVICH TSIOLKOVSKY, born in 1857 in Ijevsk, a remote village in Russia. He realized that the only practicable method for space travel is the rocket, which depends on the principle of reaction and can work in the vacuum of space. His only novel, *Beyond the Planet Earth*, was probably complete by 1895, although it did not appear in print until 1920 and its English translation was delayed until 1960. As a story, and as a literary effort, it can only be described as atrocious, but as a scientific forecast it was years ahead of its time. In his novel, the travelers used a liquid-fuel rocket motor instead of solids such as gunpowder; he described the 'step' principle of mounting one rocket on top of another (what we would call a multistage rocket). He also gave a perfectly accurate description of the causes and effects of weightlessness, or zero gravity. He was equally aware of the many problems involved in long space journeys, and he proposed to take along various types of green plants to remove excess carbon dioxide from the atmosphere inside the space-craft and replace it with free oxygen.

During the 1930s large numbers of low-cost science fiction (and detective story) magazines appeared. This generated the name 'pulp fiction', now a synonym for story-telling without sophistication. Nevertheless, some young and now established writers started in this market.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

By contrast to the bulk of pulp fiction, among the recent authors whose books contain a great deal of sound science, are the space travel visionary Sir ARTHUR C CLARKE, author of *2001: a Space Odyssey*, filmed by Stanley Kubrick. The astronomer FRED HOYLE is also an established writer, whose first and best known work of science fiction, *The Black Cloud*, includes mathematical formulae.

'Space art'

Like science fiction, 'space art' is intended mostly to convey thoughts about space and astronomy, rather than demonstrate the finer points of an art-form standing in its own right. Space art is a form of scientific illustration, akin to botanical illustration. Since the subject matter is not readily seen directly, space artists extrapolate what is known about a subject into an illustration, much as an illustrator would do when reconstructing a dinosaur from fossils or a historical site from an archaeological dig. Space artists might show what a far-off planet, double-star system or galaxy would look like if we were there in person, or how an activity in space might be implemented, such as mining an asteroid or colonizing Mars.

Space art may also incorporate fantasy elements into its genre, placing fish, flowers, etc, into a space scene for dramatic effect. An early example of this form of space art was *The Sower of Systems* (1902, The Watts Gallery, Compton; see also http://www.webmagick.co.uk/prcoll/artists/watts/index.html), a representation of the chaos prior to the formation of planets by George Frederick Watts (1817–1904). An expressionist image of the Laplace nebular hypothesis is combined with the vague form of a striding, grey-cloaked figure, as if sowing a field.

The pioneer space artist in the modern school was CHESLEY BONESTELL, who illustrated books by space-travel experts such as WERNHER VON BRAUN and Willy Ley. Modern space art is distinguished by a naturalistic method of illustration, creating detailed landscapes reminiscent of those of the American Romantic landscape painters. The subject matter and the material available both favor digital methods of work, but more traditional techniques are also common. About 120 space artists form the International Association of Astronomical Artists (http://www.iaaa.org/), founded in 1982. See also http://www.spaceart.org/index.html. Modern practitioners include David Hardy and Paul Doherty (UK), Lynette Cooke (USA), and cosmonauts Vladmir Dzhanibekov and Alexei Leonov, with Georgii Poplavski and Andrei Sokolov (Russia).

There is endless scope for space art. In the future it will be fascinating to look back at some of the speculations of the 20th century; for example, will a lunar base really be like the graceful, domed structure visualized by Bonestell? We wait and see.

Artificial Satellite

A man-made object placed in orbit round the Earth or some other celestial body. The first artificial Earth satellite was Sputnik 1, launched by the then Soviet Union, on 4 October 1957. Spherical in shape, and with a mass of 84 kg, it entered an orbit with a perigee altitude of 229 km, an apogee altitude of 947 km and a period of 96 min. Artificial satellites are used for a wide variety of roles, including astronomical observation, study of the Earth's magnetosphere and space environment, monitoring the atmosphere, weather, oceans and surface of the Earth, geodesy (study of the shape and gravitational field of the Earth), communications and military reconnaissance.

All satellites follow elliptical (or circular) orbits around their parent body. The shape and orientation (i.e. the orbital elements) of a satellite's orbit undergo changes under the action of various perturbing forces. For example, the tenuous outermost layers of the Earth's atmosphere exert a small but finite frictional drag on the motion of a satellite that causes its perigee altitude to decrease (so tending to make the orbit more nearly circular) and lead eventually to its spiralling inwards and burning up in the denser atmospheric layers. Drag forces of this kind caused Sputnik 1 to re-enter the atmosphere and burn up 92 days after it had been launched. Gravitational perturbations exerted, for example, by the Earth's equatorial bulge, or by the Moon and Sun, cause the planes of satellite orbits to precess (slowly rotate around the Earth). If the orbital inclination (the tilt of the orbital plane relative to the Earth's equator) is carefully chosen, the orbit can be made to precess at a rate that ensures that its orientation relative to direction of the Sun remains the same while the Earth revolves around the Sun. An orbit of this kind is called Sun-synchronous. If a satellite is placed in a circular orbit at an altitude of just less than 36 000 km above the Earth's equator, its orbital period will be exactly equal to the rotation period of the Earth. Because the satellite then remains continuously above the same point on the equator (and remains stationary in the sky when viewed from the Earth's surface), it is said to be geostationary. The geostationary orbit is extensively used by communications and meteorological satellites.

ASCA (Advanced Satellite for Cosmology and Astrophysics/Astro-D)

Japanese–US x-ray satellite, launched February 1993, reentered over the Pacific Ocean on 2 March 2001. During its eight-year lifetime, it provided broad-band imaging over the 1–12 keV energy range. It carried four US conical grazing telescopes and the first two CCD-based imaging spectrometers to be used on an x-ray observatory. ASCA found evidence for the creation of cosmic rays during supernovae, and played a major role in studies of x-ray binaries and gamma ray bursters. Also known as Asuka, which means 'flying bird'. (See also ASTRO.)

Ashen Light

An apparent slight brightening of the night side of Venus occasionally seen when the planet is observed as a thin crescent, near inferior conjunction, when it is nearest the Earth. The ashen light may first have been observed by Giambattista Riccioli in 1643, though it is not absolutely clear from his description that this is what he recorded as having seen; the first unequivocal description was by William Derham in 1715. The ashen light, like other observational phenomena on Venus long reported by amateur observers, such as cusp caps and the Schröter effect, has been a controversial subject: it has never been satisfactorily imaged, for example. It has been likened in appearance to earthshine (in which the portion of the crescent Moon's disk in shadow is illuminated by sunlight reflected off the Earth), though it is much more feeble, and of course it cannot have a comparable cause.

There are two possible physical explanations for the ashen light. First, it may be similar to the Earth's airglow, a faint but persistent illumination of the Earth's upper atmosphere. This is caused by the recombination of atoms and molecules that have been ionized by solar ultraviolet radiation (the atoms and molecules recombine with the electrons that were knocked off them in the ionization process). On recombination, the atoms and molecules emit a weak radiation at optical wavelengths. If the process is operating in Venus's upper atmosphere it may give rise to a stronger airglow, as the flux of solar radiation is stronger closer to the Sun. Alternatively, the ashen light may be the result of the refraction of sunlight in Venus's thick atmosphere. In theory, the atmosphere is so dense that 'super-refraction' can occur: light could be refracted all the way round the planet. There are those who maintain that it is a wholly subjective phenomenon, that the observer 'sees' the whole disk as illuminated when only the crescent is visible, particularly when cusp caps (brightenings of the cusps, the tips of the crescent) are pronounced.

Association of Universities for Research in Astronomy

The Association of Universities for Research in Astronomy, Inc. (AURA) is a consortium of educational and other non-profit institutions that operates world-class astronomical observatories. Its members are 29 US institutions and five international affiliates. For the National Science Foundation, the AURA manage the National Optical Astronomy Observatories (NOAO) and THE GEMINI OBSERVATORY. For NASA, they manage the SPACE TELESCOPE SCIENCE INSTITUTE (Baltimore, MD).

NOAO operates ground-based observatories for night-time astronomy at KITT PEAK NATIONAL OBSERVATORY (Arizona) and CERRO TOLOLO INTER-AMERICAN OBSERVATORY (Chile); and for solar research, at the NATIONAL SOLAR OBSERVATORY (New Mexico) and at Kitt Peak.

Gemini is an international project among the US, UK, Canada, Chile, Australia, Brazil and Argentina to provide two 8 m telescopes (Hawaii and Chile).

STScI carries out the scientific mission of the Hubble Space Telescope—the most powerful optical/ultraviolet observatory in space.

Asterism

A readily recognizable group or arrangement of (usually bright) stars, which are not necessarily members of a single constellation. Well-known examples are the Plough (part of the constellation Ursa Major), and the False Cross, the Summer Triangle and the Square of Pegasus, all of which comprise stars from more than one constellation. The term is also occasionally used to denote a close group of faint stars which appear to be, but are not, members of a cluster.

Asteroid Belt

The region of the solar system, between the orbits of Mars and Jupiter, where the greatest numbers of asteroids are found, is known as the *main belt*. Asteroids that orbit in this region are known as *main-belt asteroids*. The belt does not have well-defined limits. In terms of the semi-major axes of asteroid orbits, by far the greatest concentration lies between about 2.1 and 3.25 AU. These two distances correspond to two of the main Kirkwood gaps, respectively those defined by 4:1 and 2:1 orbital resonances with Jupiter. Orbiting within the 4:1 gap are the Hungaria group, in orbits peaking at around 1.95 AU, into which asteroids of various types have been gravitationally perturbed. The inner margin of this group is sometimes taken to define the main belt's inner edge, which is not circular but defined by the markedly eccentric orbit of Mars. Outside the 2:1 resonance are found the Cybele group, spread out as far as the 5:3 resonance and peaking at 3.4 AU, and the Hilda group, clustered around the 3:2 resonance at 4 AU. The main belt's outer edge is sometimes said to be marked by lone (279) Thule, named after the remote northern land of Norse legend, which orbits at 4.27 AU, a distance corresponding almost exactly to the 4:3 resonance. Within the main belt proper are several Hirayama families of asteroids, most notably the Flora, Phocaea, Koronis, Eos and Themis groups, separated by other Kirkwood gaps. These gaps are less favored regions rather than true gaps; the main ones correspond to resonances of 7:2, 3:1, 5:2 and 7:3.

In 2002, the existence of a new family of asteroids was confirmed. It is believed to be the youngest at under 6 million years old. David Nesvorny and co-workers at the Southwest Research Institute in Boulder, Colorado, recognized the 39 or so asteroids as belonging to the same family by studying their orbits. Projecting the current orbits backward in time, the researchers found that they converge about 5.8 million years ago—so this must be when they formed from the break-up of a larger body. Of the 39, two are big asteroids. One, called (832) Karin, after which the whole cluster is named, is about 19 km across; the other, called (4507) 1990, measures about 14 km. The team estimates that the parent body was at least 24.5 km across. The size of the parent body and of the fragments it produced can provide a test of theoretical models of how impacts shatter rocky bodies. The relatively fresh surfaces of the two larger fragments can also reveal what asteroids are made of, and how rapidly weathering in space pockmarks them with small craters. The Karin collision might also have been responsible for a recently discovered band of asteroidal dust.

Asteroid Discovery in History

The discovery of five of the major planets (other than Earth) in the solar system is lost to antiquity. With the acceptance of Copernicus' heliocentric model for the solar system an apparent anomaly in the spacing of the planets was noted. JOHANNES KEPLER believed that the gap between Mars and Jupiter was too large in proportion to the gaps between other pairs of neighboring planets. He concluded that an unknown planet orbited the Sun between Mars and Jupiter.

In 1766 an empirical formula for the distances of the planets from the sun was developed by Titius von Wittenburg. The formula was popularized by Johann Bode and is known today as BODE'S LAW or the Titius–Bode law. The formula is of the form:

$$A = 0.4 + 0.3 \times 2^n$$

where A is the distance from the sun (in units of the Earth's distance) and $n = -\infty, 0, 1, 2, \ldots$. The values of A determined by this formula, the corresponding planet and actual distances are shown in table 1.

Titius attributed the gap at $n = 3$ to undiscovered moons of Mars. Like Kepler, Bode argued that this gap was occupied by a major planet. The discovery of Uranus in 1781 at a distance corresponding very closely to the $n = 6$ case bolstered the belief in a missing planet. (It should be noted that Neptune is a very poor fit for the $n = 7$ case and that the 'Law' appears to be nothing more than a numerical curiosity.)

Table 1. The Titius–Bode law.

n	A	Planet	Actual A
$-\infty$	0.4	Mercury	0.39
0	0.7	Venus	0.72
1	1.0	Earth	1.00
2	1.6	Mars	1.52
3	2.8		
4	5.2	Jupiter	5.20
5	10.0	Saturn	9.54
(6	19.6	Uranus	19.18)
(7	38.8	Neptune	30.06)

The celestial police

One of the proponents of Bode's law was BARON FRANZ VON ZACH, who went as far as predicting orbital elements for the 'missing planet' and undertook a solo search to find it. After several years of fruitless searching he gave up. In September 1800, von Zach held a meeting at JOHANN SHRÖTER's observatory in Lilienthal to organize a concerted search for the presumed planet. The search was to be conducted within about 4º of the ecliptic, which was divided up into 24 sections, each section to be searched by a different astronomer. On 1 January 1801, before these celestial police could get to work, a Sicilian monk, Father GUISEPPE PIAZZI, discovered a moving stellar object in the course of constructing a star catalog. Piazzi observed the object for 6 weeks before being interrupted by illness. Although Piazzi wrote letters to various astronomers, including Bode, announcing the discovery, by the time the letters were received the new object was no longer observable. Using Piazzi's observations, various orbit computers attempted to predict where the object would be the following year, but the predictions covered 5º of sky. Prompted by Piazzi's discovery, the German mathematician CARL FRIEDRICH GAUSS developed a new method of general orbit computation. Gauss' work enabled the new object, which received the name Ceres Ferdinandea (later thankfully shortened to just CERES), to be recovered within 0.5º of his prediction independently by von Zach and HEINRICH OLBERS.

The visual era

On 28 March 1802 Olbers was checking positions of stars in the vicinity of Ceres when he discovered PALLAS. On 1 September 1804, KARL HARDING discovered the third asteroid, JUNO. Olbers noted that Juno had been discovered near to one of intersection points of the orbits of Ceres and Pallas and, believing that the asteroids were the fragments of a single object, concentrated his searching near these points. On 29 March 1807 his diligence paid off with the discovery of VESTA.

In 1845, Karl Hencke, a German postmaster, discovered the fifth asteroid, Astraea, reportedly after searching for 15 years. Hencke discovered Hebe in 1847 and other astronomers quickly began their own searches. Various observing techniques were used. Brighter asteroids could be detected by their absence on published star charts. For asteroids fainter than were shown on charts, observers had to resort to drawing their own charts and comparing drawings of the same star field at different times. By 1850 13 asteroids had been discovered. The tradition quickly developed that newly discovered objects were named immediately on (or very soon after) announcement of the discovery. The early discoveries were also allocated symbols, though this practice died out by 1855. Numbers, assigned in the order of discovery, were introduced in 1851.

The fact that numbers and names were assigned immediately on publication of the discovery announcement often led to confusion. The rapid growth in the number of discoveries (100 by 1868, 200 by 1879 and 300 by 1890) overwhelmed the capabilities of the orbit computers trying to keep track of all the objects, and as a result many objects were lost. In 1856 Hermann Goldschmidt discovered (41) Daphne. The object was followed for only four days. Goldschmidt thought he had recovered (41) the following year, but it turned out to be a new object, which became (56) Melete. This latter object was observed for only two weeks and was lost until Goldschmidt made an exhaustive search for it in

1861. Karl Luther accidentally found (41) again in 1862 but it was mistaken for a new object and for a while was numbered (74).

As more asteroids were discovered, it became clear that the majority of the objects were to be found in a belt, the Main Belt, that stretched from 2.2 to 3.28 AU from the Sun (see ASTEROID BELT). The first object discovered lying outside the Main Belt was (65) Cybele in 1861. In 1875, (153) Hilda was found at a mean distance of almost 4 AU. This was the prototype of the Hildas, objects that are in the 3:2 mean-motion resonance with Jupiter and are protected from having close approaches to that planet despite their orbits approaching quite closely.

The photographic era

Until 1892 all observing had been performed visually, using transit circles or micrometers. The introduction of photographic searches in late 1891 by MAX WOLF in Heidelberg, Germany, and shortly thereafter by Auguste Charlois in Nice, France, meant not only that observers could detect fainter objects than could be observed visually but that the photographic plate was a permanent record of an observation. Visual discoveries had been made by noting changes in star fields over the course of several hours as objects moved through the field. With long-exposure photographs, taken with the telescope tracked at sidereal rate, moving objects would betray their presence by producing short trails on the plate. The problem with photographic observation was that, at least initially, accurate positions for objects on the plates were often not measured, primarily because this was a time-consuming process requiring specialized measuring equipment. In general, approximate positions, which could be derived quickly, were obtained. Accurate follow-up observations would then be obtained by visual observers using micrometers. However, the visual observers had difficulty following the fainter photographic discoveries, and an increasing number of newly discovered objects were quickly lost.

To cope with this growing problem provisional designations were introduced. Newly discovered objects would first receive a provisional designation, a permanent number being assigned only when it was felt that the orbit of the new object was secure. Intially, the provisional designation consisted of the year and a single letter. Thus the first object so designated was 1892 A, the second 1892 B, etc. The letter I was omitted so this scheme could cope with 25 discoveries per year. The year 1892 ended with 1892 V. The letter sequence was started afresh in 1893, but the designation 1893 Z was reached in May of that year. A new series of double letters, beginning with AA, AB, … , AZ, BA, BB, etc, was instituted. This double-letter sequence was not started afresh each year; the last object discovered in 1893 was 1893 AP, the first in 1894 was 1894 AQ. The double-letter sequence was exhausted with 1907 ZZ. Rather than start a triple-letter sequence, the double-letter sequence was simply restarted with 1907 AA. The sequence was again exhausted with 1916 ZZ and a fresh start was made with 1916 AA. In 1925 a new system for provisional designations was introduced. This used a double-letter sequence and was tied to the calendar date of discovery. The first letter reflected the half-month of the discovery of the object: A represented discoveries made between 1 and 15 January, B between 16 and 31 January, C between 1 and 15 February, … , I was omitted, … , Y between 16 and 31 December. The second letter indicated the order within each half month (again I was omitted). If there were more than 25 discoveries in a half month the second letter sequence was recycled and a number was added to the designation. Thus the sequence of designations for objects discovered in the first half of January 1998 would be 1998 AA, 1998 AB, … , 1998 AZ, 1998 AA_1, 1998 AB_1, … , 1998 AZ_1, 1998 AA_2, etc.

A substantial search program had been undertaken at Heidelberg since 1891 and the primarily visual program of Johann Palisa at Vienna had been operating since 1881. Between 1874 and 1880 Palisa discovered 28 asteroids at Pola, which was then in Austria. After moving to Vienna he discovered a further 55 before he abandoned his searching in order to dedicate himself to follow-up of other people's discoveries. He resumed his searching for new objects in 1905 and discovered a further 38 by 1923. Further substantial programs were begun at Johannesburg and Simeis in 1911, Uccle (Belgium) in 1925, Flagstaff (USA) in 1929 (a search that produced the discovery of Pluto) and Turku (Finland) in 1935.

New classes of asteroid continued to be discovered: 1898, (433) EROS, the first object with a perihelion distances less than 1.3 AU; 1903, (588) ACHILLES, the first object in 1:1 resonance with a major planet (Jupiter Trojans); 1920, (944) Hidalgo, an asteroidal object with a cometary orbit; 1932, (1862) Apollo, the first asteroid with a perihelion distance less than 1 AU (see NEAR-EARTH ASTEROIDS).

The task of cataloging the asteroids had been undertaken in Germany. The principal journal for publishing discovery, positional and orbital information was the *Astronomische Nachrichten* (AN). The Astronomishes Rechen-Institut, Berlin-Dahlem, began publishing a series of rapid-alert circulars, the *RI Circulars*, in 1926. Annual collections of minor planet ephemerides were published, first in the *Jahrbuch* of the Rechen-Institut, then from 1917 separately as the *Kleine Planeten*. However, the operation of these entities was severely compromised by World War II.

In 1947 the International Astronomical Union divided up the task of cataloging the minor planets. The responsibility for publishing annual volumes of ephemerides for the numbered objects was assigned to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the Institute of Theoretical Astronomy in Leningrad, USSR (now St Petersburg, Russia). The Minor Planet Center, set up at the University of Cincinnati, was charged with tracking newly discovered objects and assigning provisional and permanent designations. The Center began publication of the *Minor Planet Circulars*, a replacement for the defunct *RI Circulars*. An early priority was the rediscovery of those numbered objects that had become lost. Of the 1564 numbered objects in 1945, the orbits of some 20% were considered to be in bad shape. New survey programs at Indiana's Goethe Link Observatory, the McDonald Observatory and the Crimean Astrophysical Observatory addressed the problem of the lost objects and helped to recover many objects. On the computational front, Paul Herget, first director of the Minor Planet Center, used the recently developed electronic computer to perform orbit computations and improvements.

Prior to 1973, all the known near-Earth objects (NEOs) had been discovered as byproducts of other astronomical programs. Two such objects had been found in 1948 in the course of the Lick Proper Motion Survey and five were found at Palomar between 1949 and 1954 during the Palomar Sky Survey. In 1973, Eleanor Helin and Eugene Shoemaker began the Palomar Planet-Crossing Asteroid Survey, the first survey whose primary goal was the discovery of NEOs.

More new classes of asteroid were found: 1976, (2062) Aten, the first asteroid with an orbit smaller than the Earth's orbit; 1977, (2060) CHIRON, the first Centaur with an orbit between the orbits of the Jovian planets. In 1978, when the Minor Planet Center moved from Cincinnati to the Smithsonian Astrophysical Obervatory in Cambridge, Massachusetts, 4390 *Minor Planet Circulars* had been issued and there were 2060 numbered objects, of which 20 or so were considered lost.

The CCD era

Just as with the change from visual to photographic observation, the change from photographic to CCD observing has meant that observers can reach fainter objects more rapidly than was possible before. One drawback that has only recently been addressed is that a CCD's field of view is much smaller than the coverage afforded by a photographic plate. A plate taken with a large Schmidt typically covers an area 6º by 6º, whereas early CCDs might cover only 6 arcmin by 6 arcmin. Modern large-format CCDs and CCD arrays are alleviating this coverage problem.

The first systematic application of a CCD to asteroid searching was by the Spacewatch project in 1981. Using the venerable 0.91 m reflector at the Steward Observatory, Kitt Peak, Spacewatch has discovered over 180 NEOs and 25 000 Main-Belt asteroids. Most of the current professional CCD searches for asteroids are optimized for discovering NEOs but sweep up many routine objects in the course of their searches. The LINEAR program (Lincoln Laboratory Near-Earth Asteroid Research team) has discovered 153 NEOs and more than 19 000 Main-Belt asteroids. Other active programs include NEAT (Near-Earth Asteroid Tracking), LONEOS (Lowell Observatory Near-Earth Object Search) and ODAS (OCA–DLR Asteroid Survey). Other professional programs, such as the Czech programs at Klet and Ondrejov, concentrate on follow-up.

New classes of asteroid continue to be discovered. The first TRANS-NEPTUNIAN OBJECTS, after Pluto, were discovered in 1992 and 1993. Some of these objects have orbits that lie well beyond the orbit of Neptune and are essentially circular, while others have orbits that are in mean-motion resonances with Neptune (principally the 2:3 resonance, as for Pluto). Although the orbits of these latter objects cross the orbit of Neptune, the resonance prevents close encounters with Neptune. The extreme faintness of the majority of these objects has made follow-up difficult and many of the objects discovered must already be classed as lost.

The availability of affordable CCD cameras to the amateur market in the early 1990s led to a resurgence of amateur activity in the field of asteroid discovery. Previously many amateurs, although possessing suitable telescopes, had been unable to observe asteroids astrometrically because they did not have the facilities for measuring photographic plates or films. CCDs and the emergence of computer programs to process CCD images have made it feasible for many amateurs to observe and discover asteroids. Other amateurs have become dedicated follow-up observers, diligently tracking down discoveries of potential NEOs by the professional surveys. Japanese amateurs have been very active since the 1970s, first photographically and then using CCDs. Major amateur activity is also found in Italy, Australia and the US.

At time of writing there are 10 986 numbered asteroids, over 164 000 provisional designations have been assigned and over 35 000 *Minor Planet Circulars* have been issued. Only one numbered asteroid remains lost. There are over 12 000 unnumbered objects with good orbits that will be eligible for numbering in the near future. More than 25 000 other objects, observed only in their discovery apparition, have orbits of varying quality and await recovery or rediscovery.

Asteroids

Asteroids are small bodies which orbit around the Sun and which show no cometary activity nor have the potential for it. The word 'small' is intended to exclude planets from the definition. All known asteroids have diameters less than 1000 km down to a few centimeters (METEOROIDS). The largest known asteroid is 1 CERES, discovered on the 1 January 1801 by Giuseppe Piazzi in Palermo, Italy with a diameter of 950 km. Asteroids are also called minor planets. The newly discovered minor body known as 2001 KX76, whose diameter makes it the largest-known minor body in the solar system (its diameter, which is not very well determined, lies in the region of 1200 km, possibly even 1400 km) is a TRANSNEPTUNIAN OBJECT (TNO). Most asteroids orbit within a confined region between Mars and Jupiter, called the main ASTEROID BELT.

Out of about 30 000 known objects, only 8500 asteroids have precisely determined orbits. Each of these asteroids has a definitive identification, consisting of a number that indicates its order of entry and a name proposed by the discoverer (e.g. '3752 Camillo' identifies the 3752nd asteroid discovered). Only preliminary orbits are available for the other 21 500; each is marked by its year of discovery and two letters indicating the date of first observation as temporary identification (e.g. '1998 BC' identifies the third asteroid (C) discovered during the second half of January (B) 1998). A thousand asteroids have been detected by the INFRARED ASTRONOMY SATELLITE (IRAS) which provided a radiometric diameter and the albedo determination of most of them. About 700 asteroids have the rotational period determined. Less than 1000 asteroids are larger than 30 km across, and of these, about 200 asteroids are larger than 100 km. Extrapolating the asteroid size distribution down to 1 km, an estimation of about one million asteroids whose diameter is larger than or equal to 1 km is obtained. The global mass of the population has been estimated to be of the order of one-thousandth of the Earth's mass.

Asteroids were considered as uninteresting 'vermin of the skies' until it was understood that they store a rich variety of information. In fact, asteroids are believed to be the remnants, either fragments or 'survivors' of the swarm of PLANETESIMALS from which the terrestrial planets were formed: the records of primordial chemical and physical processes can still be found frozen in the actual characters of asteroids. The study of these objects provides information on the nature of these primordial swarms even if differentiation and/or internal activity affected in a different way their evolution. Ground-based and *in situ* observations of asteroids show a population of solid bodies exhibiting a wide variety of chemical and physical properties: one of the most interesting characteristics of asteroids is this variety. Understanding the origin of the diversities requires the study of a large number of bodies. The information collected *in situ* on the various space mission target asteroids represents a powerful test to calibrate the techniques used in determining the chemical and physical properties of asteroids from the ground-based observations which are and will remain the main source of asteroid data.

The current knowledge on the asteroid population has been obtained mainly from the ground-based observations. Recent observations taken by the 10 m Keck II telescope on Mauna Kea, for example, reveal the presence of a small satellite orbiting around asteroid 87 Sylvia. The projected separation between primary and secondary was 0.59" in H-band images obtained on 18 February 2001 using the adaptive optics system on the 10 m W. M. Keck II telescope. Little relative motion was apparent in images obtained an hour apart (upper limit 0.02"). The brightness ratio was measured to be 420±70, implying about a 1:20 ratio of sizes. This implies that the satellite is around 7 km wide, in contrast to Sylvia, which is around 130 km wide.

Few large asteroids are included in the observational programme of the HUBBLE SPACE TELESCOPE (HST) and the first results concerning 4 VESTA are of high interest. The Infrared Satellite Observatory (ISO) observed a few tens of asteroids, allowing astronomers to obtain spectral data up to 45 μm. The National Aeronautics and Space Administration (NASA) GALILLEO MISSION approached for the first time two asteroids, 951 GASPRA (October 1992) and 243 IDA (August 1993), offering to the planetary science community the opportunity to have a close look at two S-type main-belt asteroids. The 253 Mathilde flyby (June 1997, Near Earth Asteroid Rendezvous (NEAR) mission) provided us with the first *in situ* data for a C-type asteroid.

Main-belt asteroids

The asteroid main belt occupies a doughnut-like region around the Sun which contains the orbits of most asteroids, characterized by semimajor axes (a) ranging between 2.1 AU and 3.3 AU, eccentricities (e) ranging between 0.01 and 0.3 and inclinations (i) with respect to the plane of the Earth's orbit (the ecliptic) between 0° and 35° (with an average value of 10°).

The structure of the asteroid belt is determined by gravitational interactions with both Mars and Jupiter. Because of its larger mass, Jupiter's effects are dominant and cause a depletion of objects in correspondence to the resonances, i.e. the regions where the orbital period of a body would be some exact integer ratio of Jupiter's orbital period (an asteroid 2.5 AU from the Sun is said to be at the 3:1 'resonance': that is, the body would complete exactly three orbits around the Sun for every one that Jupiter completes). Those breaks in the uniformity of the asteroid belt are called KIRKWOOD GAPS from the name of the American astronomer who identified them.

Removing the effects of secular planetary perturbations it is possible to obtain the description of an asteroid orbit in terms of its proper elements. Some main-belt asteroids have very close proper semimajor axes, proper

eccentricities and proper inclinations: they form clusters in the space of proper elements, and generally all the members of a cluster belong to the same compositional type. In 1918, the Japanese astronomer Hirayama called these clusters 'asteroid families' (see HIRAYAMA FAMILY). Analysing the 950 known asteroids, Hirayama named the identified families from the largest family member: Themis, Eos, Koronis and Flora. Since then, several other families and clans (a cluster of asteroids is called 'clan' when unequivocal family member definition and/or separation from other background objects is impossible) have been identified. Asteroid families are interpreted as the result of the catastrophic disruption of a parent body due to a collision with another smaller asteroid. If so, asteroid families represent a natural laboratory where high velocity (v~5 km s^{-1}) impacts were produced at a scale which is impossible to reproduce in our laboratories. The size distribution of family members (fragments of the parent body) is a picture of the outcomes of a collision; the chemical composition of the fragments gives an indication of the internal structure and composition of the parent body. The study of asteroid families provides information on the collisional history of the asteroid population since its formation.

The discovery of a new family of asteroids was confirmed in 2002. It is believed to be the youngest at under 6 million years old. David Nesvorny and co-workers at the Southwest Research Institute in Boulder, Colorado, recognized the 39 or so asteroids as belonging to the same family by studying their orbits. Projecting the current orbits backward in time, the researchers found that they converge about 5.8 million years ago—so this must be when they formed from the break-up of a larger body. Of the 39, two are big asteroids. One, called (832) Karin, after which the whole cluster is named, is about 19 km across; the other, called (4507) 1990, measures about 14 km. The team estimates that the parent body was at least 24.5 km across. The size of the parent body and of the fragments it produced can provide a test of theoretical models of how impacts shatter rocky bodies. The relatively fresh surfaces of the two larger fragments can also reveal what asteroids are made of, and how rapidly weathering in space pockmarks them with small craters. The Karin collision might also have been responsible for a recently discovered band of asteroidal dust.

The rotation rate versus diameter distribution of the main-belt asteroids shows that the objects with a diameter of about 100 km have rotation periods longer than those of both larger and smaller asteroids. In the hypothesis of a collisional evolution of the asteroids from a planetesimal swarm, this diameter value has been interpreted as the size where the separation between primordial larger asteroids and their smaller collisional products occurs. The spin rate distribution of asteroids with diameter larger than 50 km is unimodal and reflects the rotational behavior acquired during the primordial phases of the asteroid accretion process, while the distribution of the asteroids with D<50 km is the superimposition of three components, the 'primordial', one of fast rotators and one of very slow rotators. Disruptive collisions allow small fragments to gain angular momentum forming the fast rotator group, while a slow-down mechanism which originated the slow rotators, including 253 Mathilde, has to be further investigated.

The shapes of 50 extensively observed large asteroids have been evaluated with the Fourier analysis of the complete set of light curves and radar measurements have been used to determine the shapes of small objects. These data indicate that larger asteroids are more regular than the smaller ones. This result indicates again that the larger bodies are the remnants of the original population, which preserved in their shape the equilibrium figures, while the smaller generally irregular objects are the records of disruptive collisions.

The direction of the spin axis (pole orientation) has been determined (within an accuracy of 15% at the best) for 50 asteroids. Even if the available sample is too small to draw firm conclusions, the distribution of these pole directions seems bimodal: again a possible indication of the superimposition of two different groups of asteroids. The precise determination of the pole direction of a significative number of asteroids will lead to a better understanding of the history of the population. In fact, even though most of the spin axis inclinations of the primordial asteroids were distributed around a single value as a consequence of the accretion process, the collisions will reorient randomly the spin axes, whose distribution will be spread and flattened.

The asteroid population spreads between the orbits of Mars and Jupiter. In this zone lies the boundary separating the inner solar system (where the water in the protosolar nebula vaporized) from the outer regions (where water condensation occurred). This zone, spanning between 2.6 AU and 3.1 AU, is known as the aqueous alteration zone where spectral signatures of electron transitions, possible only in presence of liquid water, have been detected in numerous C-type asteroid spectra. This is strong evidence for the presence, sometimes in the past, of liquid water on these asteroids. The amount of water present in an asteroid is questioned but its detection would be relevant to understanding the relationships between asteroids and COMETS.

Asteroid composition

Chemical composition and mineralogy of asteroid surfaces can be determined by spectroscopy or, even if with lower precision, by multifilter spectrophotometry. Analysing with sophisticated clustering codes all the available asteroid spectra a taxonomic system has been obtained. The principal recognized classes are designated, in order of their observed relative abundance, by the letters: S, C, M, D, F, P, V, G, E, B, A (initials of the words used to roughly describe an asteroid or its spectrum, i.e. stony, carbonaceous, metallic, …). Most of the asteroids belong to the low-albedo C-type, characterized by relatively neutral spectra, exhibiting an absorption in

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

the ultraviolet wavelengths and sometimes the signatures of aqueous alteration. Their spectra match the spectra of the carbonaceous chondritic meteorites, a strong indication of similar composition (see CHONDRITES). A few asteroids (B-, G- and F-type) show C-like spectra with minor differences at the shorter wavelengths, which may reflect degrees of metamorphism of C-like material. D-type asteroids, characterizing the Trojan group, have low albedo and are redder than the C-type ones. The low-albedo P-type asteroids, predominant at 3.6 AU<a<4.9 AU, represent a transition group between C-type and D-type asteroids, their spectra are redder than C's spectra but flatter than D's spectra. The inner-belt asteroids belong to the higher-albedo S-type, whose reddish spectra are characterized in the ultraviolet by a deep absorption charge transfer band, and in the near-infrared side by the absorption band(s) of pyroxene and olivine (magnesium- and/or iron-bearing minerals: $[Mg, Fe]_2SiO_4$). These asteroids, which belong to the most abundant asteroid type, have no spectral analog in the METEORITES, even if their bulk mineralogical composition seems to fit the mineralogy of both the stony iron and the ordinary chondritic meteorites, which are the most common meteorites in the natural museum collections. One possible answer to this puzzle (known as the ordinary chondrites conundrum) may be 'space weathering'. Catastrophic collisions, solar radiation and micrometeoroid impacts could have changed an ordinary chondrite asteroid's surface enough to alter its spectral characteristics. This hypothesis seems to be confirmed by a spectroscopic study of several near-Earth asteroids which shows a continuous trend from the ordinary chondrite-type spectrum to the common S-type spectrum. This behavior can also explain the slight differences within the spectra of S-type asteroids. Some moderate-albedo asteroids have slightly reddish spectra and very high radar reflectivity; they are almost certainly made out of pure metal, probably the nickel–iron alloy which characterizes the metallic meteorites. A small number of high-albedo asteroids exhibit spectra typical of highly differentiated mineral assemblages: the surface of A-type asteroids probably contains rocks and regolith (regular lithology, indicating the dusty surface layer) formed by pure olivine; the V-type asteroids are probably all members of the Vesta family, they represent crust fragments of 4 Vesta, which is the only known intact differentiated asteroid having a basaltic lava surface. Some very-high-albedo objects have a neutral spectra resembling those of enstatite meteorites (E-type asteroids).

One of the most significant results of the asteroid taxonomy is that it reveals a distinct structure in the composition of asteroids, which vary with distance from the Sun. E-type objects are present at the inner edge of the belt and S-type asteroids populate the inner one-third of the main belt, while the C-type fill the rest of the belt. P-type predominate in the outer regions and D-type characterize the asteroids in Jupiter's orbit.

Interpreting the variation of the asteroid taxonomic types (somehow indicative of their composition) across the belt in terms of the formation processes, a few possible evolutive physical–chemical trends of the asteroid population can be sketched. All planetesimals were formed by the solid component of the PROTOPLANETARY NEBULA accreting to form a material similar to the one characterizing the D-type asteroids. This pristine material is still present in the outer belt and among the Trojans, and produced different end members (C and B, M and E, V and A-types) characterized by the variation (in space and in time) of environmental conditions in the nebula, by the internal differentiation and/or by the collisions. In figure 1, four evolutionary trends are outlined by the arrows. A first trend links the D objects to the B ones including the C-type asteroids. This sequence can be interpreted in terms of diminishing volatile content (from D to B): these asteroids seem to be composed of mineral assemblages accreted from material condensed at low temperature which experienced different thermal heating owing to the differing heliocentric distance (increasing from B to D). A second trend, connecting the primitive D-type asteroids to the G, M and E objects, can be interpreted as a progressive evolution of the pristine materials (D) toward the enstatite achondrites (E), passing through an ultraprimitive, high-carbon, low metamorphic grade C-type mineral assemblage (G) and a reduction silicate similar to the enstatite chondrites (M).

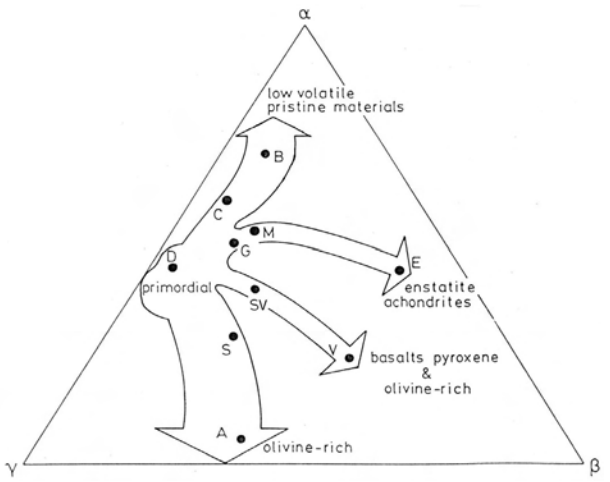

Figure 1. The asteroid compositional classes have been defined on the basis of their reflectance spectra and albedo. In this ternary diagram, the variables are grouped so that at each point $\alpha+\beta+\gamma=1$. The vertices of the ternary diagram are characterized as follows: α represents the shorter wavelength (U, B, V) regions of the asteroid reflectance spectra, β represents the longer wavelength (I, IR) regions of the asteroid reflectance spectra, and γ accounts for the asteroid albedo. The principal compositional classes are shown in the ternary diagram. Four asteroid evolutive trends are outlined by the arrows: from the 'primitive' D asteroids each trend goes towards an end member. The arrows indicate a decrease in heliocentric distance too.

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

The E-type asteroids may be composed by minerals formed when M-type bodies are differentiated. This trend describes the evolution of asteroids whose material appears to be a higher-temperature agglomeration of nebular condensate. The third and fourth trends ending at V-type and A-type respectively seem to represent lines of increasing differentiation, starting from the pristine D-type material and including the S-type objects. The metal-rich silicate surface material, characterizing these trends, may be the result of magmatic differentiation produced inside a large body (e.g. Vesta) or due to successive heating events such as large impacts. The differences of these evolution trends toward pyroxene–olivine basalts (V) and pure olivine (A) end members can take into account different collisional histories of the asteroids with respect to their hypothetical differentiation sequence.

The distant asteroids

Outside the main belt, toward the external region of the solar system, a few groups of asteroids behave in a completely different way to the main-belt ones: in fact, they reside within the main resonances with Jupiter. At 3.9 AU (resonance 3:2) there is the group of Hilda; the asteroid Thule falls in the 4:3 resonance (at 4.3 AU).

An especially interesting group, called the TROJAN ASTEROIDS, resides at the 1:1 resonance. These asteroids have the same heliocentric distance and orbital period as Jupiter does: they orbit near the two equilibrium position, known as Jupiter Lagrange points, that lie about 60° east and west of Jupiter within its orbital plane. About 200 Trojans are currently known; several thousand, larger than 15 km, are supposed to exist. While classified as asteroids on the basis of their lack of cometary activity, the physical nature of Trojans is uncertain: their optical spectra show red continua with no evidence of absorption or emission features (taxonomic type D): their albedos are very low (2–3%). Both of these characteristics are comparable with those of the few observed cometary nuclei and may be evidence for common organic compounds on the two classes of objects. As in the case of comets, the dark reddish surfaces of the Trojans could be thin rubble mantles, shielding buried ice whose sublimation rate (if exposed, e.g. by a collision) is too small to sustain an observable coma.

The Jupiter orbit marks the limit between the rocky worlds (Earth-like planets, asteroids, dust) and the ice worlds (the giant planets' satellite systems, comets, rings); in these regions it would be possible to find the transition element between asteroid and comets, which are probably the opposite end members of the same population of primeval planetesimals. In fact, a few large objects, called CENTAURS, have been recently discovered in orbits crossing the orbits of gas-giant planets. 2060 CHIRON, first Centaur discovered, is the only member of this group to display cometary activity (its comet designation is P/Koval). The Centaurs are probably a vast population of unstable, outer-planet-crossing bodies; their total number has been estimated to be 10^5–10^6 objects down to km size. All the known Centaurs are dynamically similar, but their surfaces show dramatic spectral differences: some have a completely neutral spectrum (solar like), while other exhibit the reddest spectra of solar system bodies. Are they bald comets, as well as TRANS-NEPTUNIAN OBJECTS?

The near-Earth asteroids

The NEAR-EARTH ASTEROIDS (NEAs) belong to three different groups of generally small objects residing within the inner solar system. About 500 NEAs are known and their discovery rate is continuously increasing. Of the NEAs, 5.8% belong to the Atens group characterized by a semi-major axis $a<1$ AU and an aphelion distance $Q>0.983$ AU, 48.5% belong to the Apollo group ($a \geqq 1$ AU and a perihelion distance $q \leqq 1.017$ AU) and 45.7% belong to the Amor group ($1.017 \text{ AU} < q \leqq 1.3$ AU).

The study of the physical and the dynamical properties of these objects is necessary for understanding their histories and relations with comets, main-belt asteroids and meteorites.

Understanding the dynamical evolution of NEAs is important because (i) they can have close approaches with Earth, representing a long-term danger for the biosphere and the human species, (ii) they represent the larger members of meteoroids and small interplanetary objects and (iii) physical remote-sensing observations of them have recently revealed a number of surprising features, such as high metal abundance, binary structures and tumbling rotational states which could be related to their asteroidal or cometary origin.

The general idea on NEA origin is that these objects are efficiently removed from other regions of the solar system by collisions and subsequent gravitational interactions with the planets on time scales of 10^6–10^8 yr. Since the NEAs have unstable orbits, a continuous supply of new objects is needed. Two main mechanisms have been commonly proposed for supplying the Earth-approaching population: the first assumes that NEAs are asteroidal fragments coming from the main belt, while the second supposes that a possible source for NEAs are dormant or extinct comet nuclei. NEAs of both asteroidal and cometary origin are widely believed to be continuously injected into Earth-crossing orbits through a few different resonant channels, which collect fragments randomly ejected from main-belt asteroids as a consequence of energetic mutual asteroid collisions. These objects undergo a fairly complex orbital evolution process, driven by mean motion and secular resonances, by non-resonant secular perturbations and by a sequence of close encounters with planets. Eventually, they mostly fall into the Sun or are ejected from the solar system after a Jovian encounter; only a few per cent collide with terrestrial planets. To maintain the balance between the mean rate of asteroid loss in Earth-approaching orbits and the rate of their replenishment, source rates must yield a few hundreds of new objects larger than 1 km in diameter per 10^6 yr.

So far relatively few spectroscopic observations of NEAs have been obtained because of their small sizes, faint apparent magnitudes and limited intervals of visibility. Our current knowledge of the nature of NEAs suggests that this population is characterized by a variety of surface mineralogies and includes almost all taxonomic types found in the main belt. Even if our sampling of NEAs for physical observations is strongly biased, no correlation seems to exist between taxonomic type and dimension or rotational period: both the largest and the smallest NEAs are S-type asteroids; the few C-types span a considerable range in diameter while the rare taxonomic types have a range of rotation rates as do the abundant S-types. On the basis of these data it seems that the NEA population has approximately the same proportion of S-type and C-type asteroids as the main belt. This similarity raises the question about where the dead comets, which are not expected to be a major component of the main belt, are. Several NEAs classified as C-types are apparently formed by primitive material similar to hydrous CI and CM carbonaceous chondrite meteorites. A spectroscopic survey of NEAs in the 0.45–0.9 μm range found that out of 35 objects six have spectra similar to those of ordinary chondrite meteorites, while 29 have spectral properties spanning the range between the domains of ordinary chondrite meteorites and the most common S-type main-belt asteroids. This range could arise through a diversity of mineralogies and regolith particle sizes, as well as through a time-dependent surface weathering process. In this case, if a time-dependent weathering process is active (as proposed to explain the surface variations measured in Galileo spacecraft images of 243 Ida), asteroids closely resembling ordinary chondrite meteorites would be those with the youngest surfaces.

Observations have suggested binary asteroids are common in Earth-crossing orbits. Using the world's two most powerful astronomical radar telescopes, astronomers estimate that about 16% of near-Earth asteroids larger than 200 meters (219 yards) across are likely to be binary systems. Near-Earth asteroids may become binaries when the planets' much larger gravities pull on them, distorting and sometimes breaking off a satellite. Theoretical and modelling results show that binary asteroids most likely form when the asteroids make a close encounter with the inner planets Earth or Mars, sometimes just 10 000 miles from a planet's surface.

Two asteroids made the news during 2002 because of their predicted close approach to the Earth. On 9 July 2002, MIT astronomers discovered 2002 NT7, a 2 km-wide space rock in a curious orbit. Unlike most asteroids, which circle the Sun in the plane of the planets, 2002 NT7 follows a path that is tilted 42 degrees. It spends most of its time far above or below the rest of the solar system. Every 2.29 years, however, the asteroid plunges through the inner solar system not far from Earth's orbit. After a week of follow-up observations, researchers did some calculations. There was a chance, they concluded, that 2002 NT7 might hit our planet on 1 February 2019. This made headline news, worrying some members of the public. What was not reported was that the odds of impact are 1-in-250 000. On 14 July astronomers discovered 2002 NY40. This asteroid measures about 800 meters across, and follows an orbit that ranges from the asteroid belt to the inner solar system. Its closest approach was on 18 August 2002, passing only 1.3 times farther away than the Moon, and being visible through binoculars.

Asteroid flyby

The Galileo mission on its way toward Jupiter explored the asteroids 951 Gaspra and 243 Ida, discovering around the latter the first asteroid satellite, named Dactyl; all these three are small S-type objects. 243 Ida is a member of the Koronis family. The Galileo flybys have provided images of these asteroids with a spatial resolution never obtained in Earth-based observations. The observations have shown that both 951 Gaspra and 243 Ida are of elongated shape and quite irregular, while Dactyl has a rather smooth, regular shape, which contrasts with the angularity of other known small bodies (951 Gaspra, 243 Ida, comet P/Halley nucleus, 4179 Toutatis and 4769 Castalia), but presents some aspects with comparable limb roughness with the Martian moons (PHOBOS AND DEIMOS). One prominent surface feature concerns the system of linear striae (depressions of uniform width as long as few km and few hundred meters in width with depths of probably no more than few tens of meters), which are similar to the grooves observed on Phobos and could be the signature of their origin due to a near- catastrophic collision. The most significant results were the determination of the crater size distribution on the object surfaces. From the crater frequency distribution, the age of 243 Ida was determined to be about 1 billion yr while that of 951 Gaspra was only 200 million yr. Both asteroids are covered by a layer of regolith with significant albedo and color variations.

The sequence of images where Dactyl is visible allowed us to determine its orbit as a function of 243 Ida's mass. The combination of this value with the estimation of 243 Ida's volume yields a bulk density of 2.6 ± 0.5 g cm^{-3} for 243 Ida, which is consistent with a bulk chondritic composition.

On June 27, 1997, NEAR passed close (about 1200 km) to the main-belt asteroid 253 Mathilde, providing the first flyby of a C-type asteroid.

Several ground-based reconnaissance studies were performed to characterize 253 Mathilde. A rotational period of 17.4 days has been determined: 253 Mathilde is an exceptionally slow and tumbling rotator. Spectral observations of 253 Mathilde showed its neutral reflective properties to be highly homogeneous over all the explored surface and its spectrum results comparable with those of carbonaceous and black ordinary chondrites. Whole-disk NEAR color observations between 400 and 1100 nm agree closely with these telescopic spectral results. NEAR found 253 Mathilde to be uniformly

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

bland in both albedo and color (more bland in color variations than Phobos). 253 Mathilde has a geometric albedo of 0.041 ± 0.003 at 0.55 μm. NEAR discovered five craters of diameter 19–33 km, comparable with the 26.5 km mean radius. The flyby yielded also a direct determination of the mass and a density estimate of 1.3 ± 0.2 g cm^{-3}. Comparison of this density with that of carbonaceous chondrites suggests a porosity of ~50% for 253 Mathilde.

In February 2000 the main goal of the mission, the rendezvous with the highly elongated S-type Amor group asteroid 433 EROS, was reached by means of a series of rendezvous maneuvers that slowed the spacecraft to a velocity relative to the asteroid of only 5 m s^{-1} before the insertion into orbit.

A set of detailed and precise data on three members of the S-type (951 Gaspra, 243 Ida and Dactyl), the second most abundant asteroid compositional type, is already available and within the next year new information on another peculiar S-type asteroid (433 Eros) will be obtained. On the basis of the analysis of these data it will be probably possible to determine whether S asteroids are primitive mineral assemblages, little changed since they first formed like the ordinary condrites, or material like basaltic and stony-iron meteorites that have undergone extensive melting and evolution. The first flyby of a C-type (253 Mathilde) gave an indication of a very low density of this body and of a highly homogeneous surface color. The collisions on 253 Mathilde have strongly affected its surface morphology. Are these characters common to the whole C-class?

On Friday 2 November 2002, NASA's Stardust spacecraft was tested in a flyby of asteroid Annefrank, discovering that the asteroid is about twice the size anticipated, but with a dimmer surface. Stardust flew within about 3300 km (2050 mi) of the asteroid as a rehearsal for the spacecraft's encounter with its primary target, comet Wild 2, in January 2004. The camera's resolution was sufficient to show that Annefrank is about 8 km (5 mi) in length, twice the predicted size from Earth-based observations. The surface reflects about 0.1 to 0.2 percent of sunlight, slightly less than anticipated. A few craters that are hundreds of meters across can be seen. The straight edge in the right side of the image may be an artifact of processing (figure 2).

Figure 2. Asteroid Annefrank imaged by Stardust. Credit: NASA/JPL.

Collisional evolution

After the formation of Jupiter and Mars, the planetesimal swarms orbiting between these two planets experienced strong perturbations and were widely depleted and the remnants were 'frozen' in much more stable orbits. Long-term perturbations could have produced mutual collisions, which, together with the space weathering, have been the only processes modifying the original planetesimal population.

Although the volume of space where asteroids orbit is large, and the asteroidal cross sections are small, the probability that asteroid collisions do occur in a time frame compatible with the solar system age is quite high (of the order of one collision per billion yr). Moreover, the fact that the rotation periods of asteroids follow a Maxwellian distribution may be taken as an indication that collisions were sufficiently frequent within the asteroid population to produce a collisionally relaxed state from a more massive primordial population. Many other observable characters of asteroids are presumably the effects of collisional evolution: the shape and the size distributions, the physical and chemical characteristics of families, the rotational properties.

Unfortunately the outcomes of a collision between two asteroids, depending mainly on their sizes and the relative velocity, are poorly known. Laboratory simulation of high-velocity (few km s^{-1}, of the order of the sound speed in rocky materials) impacts of a small projectile (~10^{-3} kg) on a larger target (~10 kg) cannot take into account the gravitational regime which dominates the asteroid collisions, even if scale laws are applied. What is the proportion of catastrophic disrupting collisions (where the majority of the mass of a body is dispersed) to the fragmenting ones (where the body is broken up, but the fragments re-accumulate in a rubble pile configuration)? How does the formation of an impact crater affect the chemistry of an original population asteroid? What are the effects of a collision on a rubble pile object? What is the mass loss (ejection out of the solar system or insertion in planet- or Sun-crossing orbits) induced by the collisional evolution process? The answers to these questions will allow us to understand the role of mutual collisions in shaping the present asteroid population.

On the basis of what we believe today and of the information provided by the observations, we can only draw a preliminary scenario for the processes which governed the formation and the evolution of planetesimal swarms located between 2.3 AU and 5 AU from the Sun.

The break-up of very large bodies, such as Ceres, PALLAS and Vesta, seems to have been an improbable event and the fact that some of them preserve most of their ancient crust suggests that even large impacts had limited modifying effects on the larger asteroids. These considerations imply that, if the mass of the original asteroid population was larger, the potential impactors belonged to the rather small bodies. The smallest remnants in the actual asteroid population are probably fragments of larger bodies. The intermediate-size asteroids may have undergone repeated collisions, able to partially modify their composition (formation of shock mineral assemblages, thermal processing, etc) and/or their physical properties (rubble piles, rotation period, spin axis orientation, etc), but still retaining some primordial character.

If collisions have been rare events, the scenario depicted by the observations is still the primitive one, and we are looking at a relatively pristine remnant of the primordial planetesimals. If collisions affected the original swarm all along the solar system lifetime, only the larger asteroids may preserve intact some original characters, while most asteroids reflect the effects of a thorough reprocessing, and the search for the tracks of the original imprints will have to be much more careful.

Astigmatism

An optical aberration whereby a lens (or mirror) has different focal lengths in planes that are perpendicular to each other. In general, if light rays from a point source enter a lens at an angle to its optical axis (the line passing perpendicularly through the center of the lens), the focal length for rays that lie in the plane defined by the direction of the source and the optical axis (the 'tangential' plane) will differ from the focal length for rays that lie in the plane perpendicular to this (the 'sagittal' plane). Moving outwards from the focus for tangential rays to the focus for sagittal rays, the shape of the image varies from a short line perpendicular to the tangential plane, through a circle (the circle of least confusion and position of best focus), to a short line perpendicular to the sagittal plane.

An optical system that is configured to remove astigmatism completely will suffer from field curvature (it will form sharply focused images on a surface that is curved rather than flat).

Astrid

Two Swedish microsatellites designed to investigate the near-Earth plasma environment. Astrid-1 was launched in January 1995 and carried a neutral particle imager, an electron spectrometer and a miniature ultraviolet imaging system. It ceased to operate in March 1995. Astrid-2 was launched in December 1998 to measure particle distribution, electric and magnetic field variations in the auroral region.

Astro

Set of three ultraviolet telescopes flown on the Space Shuttle in December 1990 (STS-35) and March 1995 (STS-67). Included the 0.5 m Wisconsin ultraviolet photo-polarimeter experiment, a 38 cm ultraviolet imaging telescope and the 90 cm Hopkins ultraviolet telescope. Astro-1 also carried a broad-band x-ray telescope. Astro-1 observed some 135 targets, including Comet Austin. Astro-2 discovered helium gas in the intergalactic medium by observing a distant quasar.

Astro Space Center, Moscow

Established in 1967 as part of the Institute for Space Research of the Russian Academy of Sciences. The Astro Space Center conducts fundamental research in astrophysics including cosmology, structure and evolution of astronomical objects, and the interstellar and interplanetary medium.

The center is particularly involved with developments in radioastronomy. It operates the Pushschino radioastronomy station and has an agreement to build a 70 m radio telescope on the Suffa Plateau in Uzbekistan.

The center is also developing the RadioAstron satellite, a 10 m radio telescope which will be inserted into a high elliptical orbit in order to make VLBI observations in conjunction with radio telescopes on the ground. It is part of the Spectrum series of spacecraft.

The center's Submillimetron project is under study as an astronomical payload on the Russian segment of the International Space Station. It would use a cryogenic telescope for studies at submillimeter and far-infrared wavelengths.

Astrochemistry

The study of the chemistry of, and chemical processes operating in, astronomical sources and phenomena. As far as interstellar material is concerned much of the chemistry involved is organic chemistry of light molecules (i.e. molecules containing one or more carbon atoms, possible other atoms, and in total less than, say, 50).

Astrodynamics

The study of the motion of bodies in gravitational fields, with particular reference to the motions of artificial satellites and space probes.

See also: celestial mechanics, rotation.

Astrolabe

The astrolabe (more exactly, the planispheric astrolabe, to distinguish it from less important variants) was an observing and calculating instrument that had its roots in antiquity and reached maturity in the Islamic world. Christian monasteries on the slopes of the Pyrenees made early contact with ISLAMIC ASTRONOMY, and late in the tenth century Gerbert of Aurillac (later Pope Sylvester II) may have brought an understanding of the astrolabe from Spain to the cathedral school of Rheims. Certainly the instrument itself had appeared in the West by about 1025. Its subsequent availability in the Latin Middle Ages (see DIVIDED INSTRUMENTS) did much to encourage a quantitative science of astronomy.

The basis of the instrument is a heavy disk of brass that can be suspended from a ring so as to hang vertically. On the back of the instrument is an observing bar that pivots about a central pin; the observer measures the altitude of a celestial body by sighting along the bar and reading the altitude from a scale in degrees engraved around the circumference.

The front of the instrument is for calculation. To allow the instrument to be used at different latitudes, a set of alternative disks was supplied, and the user arranged them so that the most suitable latitude disk was face up within the recess provided. On this disk were engraved circles associated with a plane representation of the celestial sphere. If the celestial sphere is imagined as projected from the South Celestial Pole onto the plane of the equator (represented by the latitude disk), then the circle that is the celestial equator projects into itself, and the North Celestial Pole into the center of this circle. Points on the northern hemisphere project into points of the plane that are internal to the celestial equator, and those on the southern to points external. Because the brass astrolabe was necessarily of finite size and northern observers had little interest in skies south of the Tropic of Capricorn, the projection of this tropic was made the perimeter of the latitude disk.

The observer's zenith projected into a point, and circles of equal altitude in the sky as seen from his position projected into circles enclosing (but not centered on) this point, while arcs of equal azimuth projected into arcs passing through this point.

Thus far the projection incorporated the principal fixed circles in the sky and the coordinate circles or arcs associated with observations by the observer. To represent the rotating heavens, and in particular the ecliptic path of the Sun and the positions of the stars, the instrument maker provided a further disk (the *rete*) superimposed on the latitude disk and rotating about the central pivot (thus matching the rotation of the sky about the North Celestial Pole). To avoid obscuring the latitude disk, the maker cut away as much of the rete as possible, leaving little more than a network of labelled star-pointers together with a circle that represented the ecliptic.

The sky rotates with one degree of freedom, and therefore a single observation (the ambiguity between rising and setting presenting little difficulty in practice) is sufficient to determine the correct position of the rete at any given time. So, for example, the observer might first observe the altitude of Sirius, and then, having retreated to the warmth of his study, he would rotate the rete until the point representing Sirius was correctly positioned above the relevant circle of altitude. All the other stars would then be correctly positioned likewise, and he could determine, for example, which were now above the horizon and which below.

On Western astrolabes the back of the instrument contained not only the circular scale in degrees for measuring altitudes, but a second circular scale with the days of the year, placed so that the appropriate position of the Sun on the ecliptic was aligned with the calendar date. Knowing in this way the current position of the Sun on the ecliptic, the user could imagine an appropriate mark on the representation of the ecliptic. A brass bar located on top of the rete and also rotating about the central pivot could then be placed across this mark, so as to indicate the time on a 24 h scale located outside the perimeter of the latitude disk, and in this way the instrument became a clock that told the time both night and day. Thus the night-time observation of Sirius that had allowed the rete to be correctly positioned also gave the position of the Sun and hence the time of the observation. In the daytime, observation of the Sun itself gave the same information. Similarly, by rotating the rete the user could establish at what time a particular event—the rising of Sirius, for example—would occur.

As an observing instrument accurate to a small number of degrees, the astrolabe could also be used to measure the altitudes of the planets, and this fostered a revival of planetary astronomy in the Latin Middle Ages that was to culminate in the *De Revolutionibus* of COPERNICUS. However, its primary use was in astrology, especially as a guide to medical treatment.

Astrology

Astrology is the theory that the planets, the Sun and the Moon, as well as the 12 'zodiacal signs', combine in various, ever-changing configurations with respect to each other and the local horizon to influence 'sublunar' events.

In astrology, as in classical astronomy before the acceptance of the Copernican hypothesis, it was assumed that the Earth was positioned in the center of a finite universe, and that the Earth's center was the center of the spheres of the celestial bodies—in upward order from the Earth, the Moon, Mercury, Venus, the Sun, Mars, Jupiter, Saturn, the 'fixed' stars, the ecliptic and, often, the 'prime mover'. The motion of these 10 spheres was, according to ARISTOTLE, circular and uniform in accordance with the nature of the element, ether, of which they consisted. The motions of the four elements that constitute the sublunar world were linear with respect to the center of the Earth, the elements earth and water moving 'down' towards the center, and the elements air and fire moving 'up' away from the center. The circular motions of the celestial spheres disturb the linear motions of the four sublunar elements, thereby causing change in and on the Earth and in the surrounding layers of water, air and fire. The resulting combinations of elements form the basic materials out of which terrestrial and atmospheric bodies are shaped, which are then continuously further affected by the motions of the celestial bodies and by subsidiary interactions of sublunar bodies. Thus the UNIVERSE is a vast but finite machine powered by the natural motions of its five constituent elements, among which the ETHER with its regular circular motion has the major effect, and astrology is the science that investigates the operations of this universal machine.

Celestial omens

In ancient Mesopotamia and in the many cultures influenced by it many celestial phenomena—eclipses, conjunctions of the Moon and the planets with each other and with the stars, a large number of phenomena due to the distortion of light as it passes through the atmosphere, and other appearances—were regarded as messages sent by the gods to warn the rulers of men or collective groups of men of impending disaster or good fortune. The interpretation of these celestial omens was also a science by which men of great learning strove to provide useful advice to kings and other government officials. The experience of these learned readers of omens led to the recognition of the periodic behavior of the Sun, the Moon and the planets, and ultimately to the development of mathematical methods of predicting the phenomena themselves (which, because of their predictability, should then have been, but were not, no longer regarded as messages sent by angry or well-pleased gods). It also led to the development of some techniques of interpretation of celestial omens that were carried over into astrology, including that of predicting the fate of a person from the positions of the planets at his or her birth or computed conception. In practice, these protohoroscopes of the last four centuries BC were not a part of astrology since the phenomena were ominous rather than effective and since the elaborate geometry used in astrology was not a factor in their interpretation.

The thema or horoscope

The basic tool used to interpret the influences of the celestial bodies at any given moment—say, that of a native's birth—was the diagram called the thema or horoscope. This diagram represents the ECLIPTIC, divided into 12 zodiacal signs of 30° each, as a circle or a quadrilateral with the four cardinal points marked on it—the ascendant on the eastern horizon, the descendant on the western horizon, the midheaven to the south at a point computed by using the local oblique ascensions, and the antimidheaven 180° opposite it to the north. Between and at these cardinal points are located the cusps of the 12 astrological places. The zodiacal signs are divided into various subdivisions: decans of 10° each, twelfths of 2°30′ each, and terms of varying length, usually five to a zodiacal sign. The longitudes of the planets are noted in the thema, which locations reveal their configurations (aspects) with each other—conjunction, sextile (to 60°), quartile (to 90°), trine (to 120°) and opposition (to 180°)—which may be computed by various mathematical formulae so as to be measured in oblique or right ascensions or so as to accommodate the planets' latitudes. Moreover, various lots (defined as the distance between two real or imaginary celestial bodies measured off from a third) and the prorogator (computed in various ways) are noted on the thema, as may also be such fixed points as the exaltations (points of maximum effectiveness) of the planets and the four triplicities (Aries, Leo, Sagittarius; Taurus, Virgo, Capricorn; Gemini, Libra, Aquarius; Cancer, Scorpion, Pisces).

Domains of influence

Each zodiacal sign is classified according to numerous categories: masculine–feminine; odd–even; animal–human; village–forest; etc. Moreover, there are zodiacal melothesias, assigning different parts of the human body to the zodiacal signs; topothesias, doing the same with types of terrain on the surface of the Earth; lists of the animals, the professions, the metals, the jewels, the colors, etc of the zodiacal signs. Each of the signs has especial influence over the categories assigned to it. The triplicities, being four in number, are each associated with a cardinal direction and an element.

The 12 astrological places each have dominion over a certain aspect of the native's life (bodily form; inherited wealth; siblings; parents; children; illnesses; marriage; manner of death; travels; profession; gain; loss) or of an enterprise undertaken. They are influential in their domains in accordance with the zodiacal signs they overlap and the presence within them or aspects to them of the planets and the lots.

The seven planets also (nine in India, where the ascending and descending nodes of the Moon are included) have each their own domains among physical types of humans and animals as well as psychological types, and each is related to types of terrain, of animals, of plants, of minerals, etc, and to an element and its humors (fire–hot and dry; water–cold and humid; air–hot and humid; earth–cold and dry). They are also classified as male or female, and as benefic, malefic or neuter. As the seven planets revolve through the zodiacal signs, and they in turn revolve about the stationary Earth, the influences they project into the sublunar sphere are constantly changing, creating ever-new events and transformations on Earth. These can, according to astrological theory, all be predicted on the assumption (alleged to possess some empirical foundations) that the accepted domains of the celestial bodies' influences are indeed correct. Historically, the system did not remain static; it was simply not complex enough to differentiate between the apparently limitless variations of human experience. In order to accommodate these variations, astrologers—especially those of India and Islam, who were duly followed in medieval Europe and in Byzantium—devised many more subdivisions of zodiacal signs in order to multiply the potential number of the effects of a planet, invented elaborate methods for assigning a numerical weight to the influence of each planet and expanded the number of effective bodies by introducing new lots.

Types of astrology

The paradigmatic type of astrology is genethlialogy, the science of interpreting the themata of nativities or of computed times of conception, probably invented in the 1st century BC in Ptolemaic Egypt. Such predictions can be and were also applied to animals and even plants. Although in theory the predictions are unique for each moment at a given locality, many astrologers wisely advised neophytes to learn something about the social and economic status of the native's family before attempting to describe his or her future life. A branch of genethlialogy is continuous horoscopy, which allows for a life-long usefulness of the astrologer. Since the planets and the ecliptic do not cease their revolutions, one can find their changing influence on the original life-pattern determined from the birth horoscope by casting a new horoscope for every anniversary of the birth, or for the beginning of every month or even day of the native's life, and one can also compute the time when each planet transits to another zodiacal sign or astrological place, thereby altering its effects, and one can watch the imaginary motion, in oblique ascensions, of the prorogator through different planets' terms and past different planets' bodies and aspects.

Catarchic astrology, invented simultaneously with the genethlialogical version, allows one to predict the course of some human undertaking from the horoscope of the moment of its inception. There are two major subdivisions of catarchic astrology, relating to marriage and to warfare. Some aspects of medical astrology are also catarchic, although other aspects depend on genethlialogy.

These two basic forms of astrology were transmitted from Greco-Roman Egypt to India in the 2nd century AD. In India interogational astrology was developed from catarchic astrology. In this form the astrologer answers specific questions posed by his client on the basis of the thema of the moment the question was asked. This clearly raises serious questions about the general theory of astrology; for either the client is exercising free will in determining when he or she will ask the question, so that there ceases to be a purely physical connection between the celestial bodies and the terrestrial event, or else his or her choice is determined by the stars and therefore could, in theory, be predicted by astrology and answered without recourse to a new thema.

These three types of astrology were transmitted from India to Sasanian Iran in the 3rd–5th centuries AD, as were the first two from the Roman Empire. The Sasanians added to them a fourth major type, historical astrology, which uses forms of continuous horoscopy (e.g. the horoscopes of the commencements of all or of selected years) as well as conjunctions of the two furthest of the then known planets, Saturn and Jupiter, or conjunctions of the two malefic planets, Saturn and Mars, in Cancer. Practitioners of historical astrology also cast the horoscopes of the coronations of kings and other historical beginnings, in these cases following the rules of catarchic astrology.

The question of astrology's validity

Clearly, whatever claims were made for an empirical basis, this whole theory is founded on arbitrary assumptions concerning the relationships between the individual zodiacal signs and planets and the physical parts and psychological aspects of sublunar objects and beings, as well as on a subsequently disproved theory of the COSMOS. In antiquity the arguments against astrology's validity were largely based on practical problems: how to explain the often great differences between the physical and mental attributes of twins and their separate lives; how to explain the simultaneous deaths of large numbers of people of different ages in a battle or natural catastrophe; how to be sure of the exact moment of birth and of the local ascendant at that moment. The Christian Church, and later Islam, frequently condemned astrology because it denies man or woman free will and so deprives him or her of the capacity to gain salvation through his or her own efforts and because it makes God irrelevant to the universe, which is an eternal and automatic machine. None of these arguments seriously damaged the credibility of astrology among many, nor has the collapse of the geocentric theory, although that has discouraged many scientifically minded persons from granting it any credence. Like several other current sciences that in fact continuously demonstrate their inability to predict the future accurately, astrology is still able to attract and to retain the patronage of innumerable clients.

Astrometric Surveys

The meaning of astrometric surveys

Applied to astronomy, a survey has been defined as 'an examination for purposes of ascertaining the quality or quantity of something. Depending on the nature of the survey, this may mean looking at a large number of objects in an attempt to discover those meeting specific criteria.' (Warren 1992).

What is not specified in the above definition is whether the survey of objects meeting the established criteria must be the result of an observational program or a search in the literature. Although the term survey in astronomy is quite often applied to observational programs, some recent astrometric surveys have made use of the material published in the available literature. What is more, the new generation of astrometric surveys may even be carried out over the web (see 'The new millennium', below). Therefore, when speaking about surveys, we may refer to observational astrometric surveys, bibliographic astrometric surveys and the coming computer astrometric surveys.

When can a survey be called astrometric? In other words, what are the main characteristics of an astrometric survey? To answer these questions, the first point to consider is what is astrometry? Astrometry is that part of astronomy dealing with the positions (absolute or relative), motions and trigonometric distances of celestial objects (see also ASTRONOMY: TELESCOPES AND TECHNIQUES). Each of these parameters has its own importance in the study of our stellar environment.

What should be the accuracy of a given astrometric parameter? It is important to define the level of accuracy because that value will, to some extent, determine the quality of the survey. For example, no one would attempt to carry out an astrometric survey today with the accuracy level of the Durchmusterungs (Bonner, Córdoba or Cape) since such a level would be extremely low for today's standards; however, the importance of these surveys at the time they were published is undeniable.

What is an astrometric survey? Putting all the above considerations together, an astrometric survey can be defined as a search oriented to find those celestial objects meeting a given accuracy in their absolute or relative positions, motions, or trigonometric distances. Some of these surveys have been or are being conducted with ground-based meridian circles, ASTROLABES or astrographic telescopes, while others—already completed or planned for the future—have used or will be using space-based instruments.

Brief historical account of astrometric surveys

The compilation of catalogs including positions and PROPER MOTIONS is among the best-known activities in astrometry. In the early beginnings of astronomy, providing positions of celestial bodies was a real necessity for many of the ancient cultures. With roots dating back to the pre-Greek civilization, astrometry provided the information for computing solar and lunar eclipses and, more importantly, for the determination of time.

Thanks to the positions obtained by his predecessors and his own observations, HIPPARCHUS was able to identify the precession of the Earth's axis of rotation. It was also thanks to old and new astrometric catalogs that Edmund HALLEY introduced—in 1718—the proper motion of the stars. Some years later, in 1802, HERSCHEL noted the relative orbital motion for the two components of Castor, marking the beginning of double-star astrometry. The next landmark appeared in 1838, when Friedrich Wilhelm BESSEL was able to determine the PARALLAX of 61 Cygni. The history of astrometric catalogs—taking the detector used in the observational process as a parameter—could be divided in three different periods: visual (with or without an instrument), photographic and CCD based (Earth- or space-based instruments). With regard to the epochs in which the different detectors were employed, it could be said that, in general, the unaided human eye was used as a detector from the very beginning of astronomy until the year 1610, when GALILEO GALILEI started to use the telescope during his observations. After 1610, meridian circles or some other types of optical instruments were used to aid the human eye in most of the astrometric surveys. This approach lasted for over 300 years.

One of the first catalogs ever compiled was prepared by Hipparchus. It was completed around 129 BC (there has been a debate concerning the number of objects listed by Hipparchus: some historians have agreed that there were 1080 stars while others consider that there were only 850 stars). Hipparchus' catalog was included in Ptolemy's Almagest, the biggest compendium of astronomy of that time, which was in use for about 14 centuries. Previous compilations by Greek and Chinese astronomers date back to roughly 300 BC and even to 360 BC (Eichhorn 1992). During the Middle Ages the most important compilation worth mentioning—although it may not be considered a catalog in the current sense—is called the Alfonsine Tables, compiled under the reign of Alfonso the Wise and first published—probably—after 1277. Actually, the real purpose of the Tables was to offer a means to calculate the positions of the planets; one of the main users of the Alfonsine Tables was Copernicus (Gingerich 1992). Another catalog compiled in the first half of the 15th century was that of ULEGH BEG.

TYCHO BRAHE is among the first astronomers who—using his mural quadrant—started to make accurate systematic observations during the pre-telescope years. His observations include the supernova of 1572, the comet of 1577 and a large collection of positions for Mars. After Brahe's death in 1601, these positions were used by his

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

assistant JOHANNES KEPLER and were a key element in the derivations of Kepler's laws.

With the introduction of the telescope as an astronomical instrument, many zone (independent) catalogs started to be observed by means of meridian circles. Most of the observational surveys of the early to mid-1800s were limited to some specific areas and there was no agreement on the 'system' that should be used (the convenience of having a system in the modern sense of the term to which positions have to be referred was proposed in the late 1800s). One of the first attempts to carry out a comprehensive survey was started by ARGELANDER with the observation of the zone from +80° to –2°. The zones from –2° to the south pole were added later. This first survey—known as the Durchmusterungs—was made in three parts: the Bonner Durchmusterung, the Córdoba Durchmusterung and the Cape Photographic Durchmusterung.

The most important work of the early years of the 20th century was the General Catalogue (GC) (Boss 1937), a preliminary version of which was published by Lewis Boss in 1910. This version was called the Preliminary General Catalogue (PGC), and it was later completed with the publication of the GC in 1937, which included over 33 000 stars. What is important to highlight about the PCG/GC project is Lewis Boss' ultimate aim: the construction of a fundamental system. This goal was finally accomplished by his son, Benjamin Boss. In this sense, the N30 catalog compiled by Morgan (1952) is also worth mentioning.

For a detailed historical account of astrometric catalogs see Eichhorn (1974, pp 101–278). Also see Jaschek (1989) for a discussion of the different types of catalogs.

When the photographic plate was finally accepted by the astronomical community as a detector (around 1880), the photographic astrometric surveys started to develop. Curiously, the first observing program with the newly introduced astrographic telescope (the accompanying instrument to the photographic plate) was the observation of the biggest international project of the last years of the 19th century: the Astrographic Catalogue (AC). This program received a grat deal of criticism, as many considered that it was too early in the development of astrographic telescopes and photographic plates to undertake such a large project using a rather small (2° × 2°) field of view. However, from a current-day perspective, the launch of the AC can be regarded as a positive initiative. Thanks to that decision, astrometry now has a marvellous set of over four million first-epoch positions (nowadays 100 years old) for high-accuracy proper motion determinations.

Although the AC—in itself—should be considered an observational survey, it was never used as such until very recently. In this sense, two major catalogs have been produced using the published coordinates of the AC: the 4 Million Catalogue (Gulyaev and Nesterov 1992) and the AC2000 (Urban *et al* 1998). The former combined the AC with the Hubble Space Telescope Guide Star Catalogue (GSC) in order to compute proper motions; both sets of positions (AC and GSC) were reduced into the PPM system. In addition to positions and proper motions, the 4 Million Catalogue also provides cross identifications with other surveys such as the Durchmusterungs, PPM, SAO and VARIABLE STARS. The AC2000 contains over four and a half million positions (and magnitudes) with an average epoch of 1907. In order to reduce the published x, y coordinates of the AC, Corbin and Urban (1990) first compiled the ACRS to be used as the reference frame. The positions of the AC2000 are on the Hipparcos/ICRS system. A more recent reanalysis of the AC2000 has yielded the AC2000.2 (Urban *et al* 2001).

Apart from the 4 Million and the AC2000, there are some other surveys that have made use of the AC. Of these, the PPM was the first.

For a detailed and enthralling history of the Astrographic Catalogue see Eichhorn (1974, pp 279–323).

While the observation of the AC was underway, other photographic—zonal—surveys were also in progress: the Yale zones and the AGK2 (the AGK1 was observed with meridian circles). In total, Yale published 30 catalogs with epochs ranging from 1928 to 1942. The first volume of the Yale zones to appear included over 5000 equatorial stars (Schlesinger *et al* 1926); the last one (the zone from –60° to –70°) suffered a number of delays and it was not published until 1983 (Fallon and Hoffleit 1983). The last one of the AGK series was the AGK3 (Dieckvoss 1971). Because of the development of artificial satellites and the urgent necessity of tracking them, by the mid-1960s, the need was felt to have a general comprehensive compilation embracing the existing catalogs into a single one. The realization of such a project was undertaken by the Smithsonian Astrophysical Observatory, and in 1966 the 'Star Catalogue' subtitled 'Positions and Proper Motions of 257,997 Stars for the Epoch and Equinox of 1950' became available to the astronomical community. The catalog, known as SAO (see Haramundanis 1966 for details of the construction of the catalog), covers from +90° to –90° and it was for many years the standard reference frame for the reduction of most of the photographic plates. Thousands of positions of asteroids, comets, major planets and natural satellites were obtained using the SAO as a primary reference catalog for stellar positions and proper motions. However, as is well known, time—through the proper motions—is always responsible for the degradation of any astrometric catalog. The SAO was no exception, and, after being in use for over 25 years, it was replaced by the PPM (Roeser and Bastian 1993). The PPM—also covering the entire sky—lists over 375 000 positions and proper

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

motions in the J2000/FK5 system. Typical values of the r.m.s. errors in the northern hemisphere are 0.27 arcsec in the positions at epoch 1990 and 0.42 arsec century^{-1} in the proper motions, while the corresponding figures in the southern sky are much better (Roeser *et al* 1994). The main improvement of the PPM over the SAO was made through the inclusion of the century-old AC data. After its publication, the PPM replaced the SAO as the reference frame for most of the photographic astrometry programs. Because of the discontinuation of photographic plates and the advent of CCD detectors, the PPM has now been replaced by catalogs of much higher density.

While some astronomers were engaged in the observation and reduction of large catalogs of positions, others focused their attention on the search of stars with high proper motions. According to Luyten (1963), this type of project benefited greatly from the introduction of the blink microscope. Several surveys for stars with large proper motions were carried out by Luyten (1970), resulting in the detection of a large number of objects. Subsets of these surveys and/or a revision or reorganization of them were published as the Luyten Half Second (LHS), Luyten Two Tenths (LTT) and the New Luyten Two Tenths (NLTT) surveys. Most of the results were published by the University of Minnesota, Minneapolis (USA). Among the large proper motions surveys, the Lowell Proper Motion Survey (Giclas *et al* 1971) is one of the most important, as it includes finding charts for each star.

In order to present a more complete historical account of astrometric surveys, a reference should be made to the Hipparcos mission. The Hipparcos satellite—funded and operated by ESA—was the first space experiment dedicated to astrometry. Its primary goal was the determination of accurate positions, proper motions and parallaxes of 118 218 stars. The accuracies of the astrometric parameters are roughly 1 mas for the positions and parallaxes and 1 mas yr^{-1} for the proper motions for stars as faint as magnitude 10. The positions and proper motions of the Hipparcos Catalogue (ESA 1997a) are the optical realization of the ICRS and they constitute the most accurate large astrometric catalog ever observed. The importance of Hipparcos is that it has for the first time enabled astronomers to calibrate accurately the luminosities and masses of many nearby stars and to study the kinematic structure of the Galaxy in the solar neighborhood. The impact that Hipparcos has had in astronomy can be appreciated in the proceedings of the Hipparcos Venice '97 meeting (ESA 1997b) which contains nearly 200 research papers based on Hipparcos' data.

As part of the Hipparcos mission, the 'stars mappers' of the satellite were used for the construction of a less accurate catalog: the Tycho Catalogue. A re-analysis of the original data of this experiment yielded the Tycho-2 Catalogue (Høg *et al* 2000) which has become one of the standard compilations in the astrometric reduction of the CCD frames (mainly in the meridian circle observations). More details about HIPPARCOS and the HIPPARCOS AND TYCHO CATALOGS are given in other articles.

In the last 14 years, the history of astrometry can be said to have been signaled by two main events: the first one was the launch of the above-mentioned Hipparcos mission in 1989; the second one was the establishment—on 1 January 1998—of the International Celestial Reference System (ICRS) as the new reference system, thus bringing to an end the regime of the FK series. With this major change, and for the first time, astrometry's reference frame—the International Celestial Reference Frame (ICRF)—to which positions have to be referred, is based on 212 extragalactic RADIO SOURCES observed with very-long-baseline interferometry (VLBI) techniques (see Ma *et al* 1998). An important review concerning the adoption and implications of this change has been made by Feissel and Mignard (1998).

Today, after significant achievements through its history and thanks to the use of a new generation of extremely high-quality Earth- and space-based instruments, astrometry is undergoing new and profound changes. From the multiple-fiber-fed instruments on Earth to the most advanced and sophisticated satellites, there is a common need for better positions of celestial objects and astrometry, once again, has to provide accurate positions, proper motions and stellar parallaxes. The fact that some of the coming space missions need to rely on ground-based astrometric observations for their success illustrates the importance of the new astrometry.

In order to meet the requirements imposed by today's astronomy, new astrometric surveys oriented to providing the classical parameters are underway. Because of the increasing power in both computer and detector development, the current projects are growing in size (more than 500 million entries in general) and accuracy (a few mas). Some of these new surveys are based on new observations, while many others are making use of the extensive material provided by the databases, thus bringing up a new way of doing astronomy in general: the virtual observatories (see also ASTROMETRY: HISTORY).

Major achievements

Over the last few years there has been outstanding progress in most of the astrometric projects. These can be summarized as follows.

Positions and proper motions

Since the CCDs became the standard detectors in almost every astronomy project, there has been a real need for catalogs of positions (and, ideally, proper motions as well) containing a large number of stars. In some sense it

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

could be said that astronomy is—again—experiencing a similar situation to the one that occurred in the mid-1960s when the SAO was published (then replaced by the PPM). Because of the low number of objects they include (by today's standard), these two catalogs are now inappropriate for the astrometric reduction of most CCD frames.

In order to overcome the problem of having too few stars per square arcminute, it was necessary to compile much larger catalogs. The first step in this sense was taken by the Hubble Space Telescope Guide Star Catalogue (GSC) by Lasker *et al* (1990), which now has been superseded by the GSC II in both quantity and quality.

Another major compilation worth mentioning is the USNO-A2.0 (Monet *et al* 1998), which is the standard—at least for the moment—for the astrometric reduction of most of the CCD frames. A subset—called USNO-SA2.0—containing about fifty million stars is mostly used in the reduction of minor planet and comet CCD frames.

As usual, after a catalog is published, its contents are analysed and externally compared with other compilations for a final evaluation of quality. The USNO-A2.0, as well as the GSC II, is no exception. A very detailed analysis of the USNO-A2.0 has been performed by Assafin *et al* (2001). In this paper, the authors have compared some of the positions of USNO A2.0 against the ones observed with the Valinhos CCD Meridian Circle (Viateau *et al* 1999). An extension of the USNO-A2.0 catalog, the USNO-B, is currently in progress (see Monet 2000). It will include proper motions and star/galaxy classifications.

One step above the USNO-A2.0 (at least from the quantity point of view) is the GSC II. When finished it will have close to 109 entries with a typical error of 0.3 arcsec (the worst case is between 0.35 and 0.65 arcsec for stars fainter than 16th magnitude near the edge of the plate). A preliminary version of this compilation, known as the GSC 2.2, is ready for use, listing more than 430 million stars. The positions of the GSC II, as well as the GSC 2.2, are in the system of the ICRF. The mail goal of the GSC 2.2 is to support the opration of both GEMINI and VLT telescopes.

Momany *et al* (2001) have performed an external comparison of the GSC 2.2. As part of the ESO Imaging Survey (EIS) these authors have compared the positions of GSC 2.2 with those reported by others in the area of some open clusters.

Probably the most recent project to have accomplished part of its goals is the USNO CCD Astrograph Catalogue (UCA). A preliminary catalog—the UCAC1—in the ICRS contains over 27 million stars with a positional precision of less than 20 mas for objects in the magnitude range 9–14. Preliminary proper motions from a variety of sources are also given. The UCAC1 will be superseded by the UCAC2—covering from –90° to +30°—which will be available by mid-2002. When finished, the UCA project will provide the first astrometric catalog entirely observed with an Earth-based telescope using a CCD as a detector.

In order to improve the quality of the proper motions to be included in the UCAC project, the AGK2 plates (more than 70 years old at this moment) are being re-measured at USNO and will then be combined with modern positions (see Winter and Holdenried 2001). Various progress reports on the UCAC project can be found in Zacharias *et al* (2000a, b, 2001).

Among the projects oriented towards the determination of absolute proper motions, two programs have provided a large number of data: the Northern Proper Motion Program (NPM) developed at Lick Observatory (Klemola *et al* 1987) and the Southern Proper Motion Program (SPM), which is being developed by a Yale University (USA)–National University of San Juan (Argentina) consortium. The first batch of the NPM—called NPM1—was released in 1993. It contains positions, proper motions and two-color photometry for 149 000 stars outside the Milky Way. The NPM2 (Jones *et al* 2000), the second batch of the series, will contain around 300 000 stars located in the Milky Way. Since reference galaxies are 'absent' in the Milky Way sky, the Hipparcos Catalogue is being used to link the NPM2 proper motions to the (absolute) system defined by NPM1. The NPM2 will be released in 2003.

The first-epoch observations of the SPM were started in 1965 and lasted until 1974. The second epoch, using photographic plates, began in 1987 and was stopped in 1993 owing to the lack of photographic plates. Now the observation of the second epoch will be resumed by using two CCD cameras (van Altena 2002). Two major results from the SPM have been released: the SPM 1.0 (Platais *et al* 1998) and the SPM 2.0 (for a detailed analysis of the SPM 2.0 proper motion system and its relation with Hipparcos see Zhu 2001). Also, as part of the SPM project, a catalog of positions for approximately 30 million stars has been announced (Platais *et al* 2001b).

Results from another major digitization process of photographic plates have recently been published. The astrometric properties of the SuperCOSMOS survey have been analysed by Hambly *et al* (2001). By comparing the first release of data—the south galactic polar cap—with external data sets, they have concluded that the positions (in the ICRF via the Tycho 2) are accurate to better than ±0.2 arcsec at magnitudes J, $R \sim 19$, 18 while the proper motion measurements are shown to be accurate to typically ±10 mas yr $^{-1}$ at the same magnitude level.

Open-cluster astrometry has also received very close attention. A number of articles on the subject have been published in the past few years. Some of them have

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

made use of the extensive databases available while others have relied on new observations. In both cases—database analysis or new observations—the outcome has been the determination of positions, proper motions and magnitudes for a large number of stars. An important survey, which is being conducted with the WIYN telescope, is the WIYN Open Cluster Study (WOCS). Results from this survey have been published by Platais *et al* (2001a, c).

There is a significant number of contributions to the open-cluster studies that have used databases and highly accurate astrometric catalogs. Among them are Baumgardt *et al* (2000); Dias *et al* (2001), Sanner and Geffert (2001) and Masden *et al* (2002).

WEBDA is an updated collection of open-cluster data maintained by Jean-Claude Mermilliod at the Institute of Astronomy of the University of Lausanne (Switzerland). The database has very simple features that ensure easy retrieval of data and offers astrometric, photometric and spectroscopic information. Miscellaneous data (such as membership probabilities) and bibliographic references are also included.

Double stars

The most important compilation of DOUBLE STARS is the Washington Double Star (WDS) catalog. The main advantage of the compilation is that it is updated on a daily basis. A series of four CDs has been recently published by the US Naval Observatory. Volume I (Mason *et al* 2001) contains the basic astrometric data (coordinates for J2000, position angle, separation, etc,) for over 84 000 systems. The second volume (Hartkopf *et al* 2001) is a collection of 1465 orbits. Volume III (Hartkopf *et al* 2001) is actually the Third Catalogue of Interferometric Measurements of Binary Stars. Volume IV (Worley *et al* 2001)—the last of the series—is a collection of magnitude differences for over 10 000 systems.

Since the early 1980s, CHARA has been the leading survey group using speckle techniques to measure the separation and position angles of double stars (basic information for stellar mass determinations). To date, 19 catalogs with position angles and separations for approximately 10 000 stars have been published (Mason *et al* 1998). The group has finished the construction of an interferometric array of six 1 m telescopes to resolve binaries with angular separations down to 0.2 mas. The CHARA array will be fully operational sometime in 2002. Progress reports on this array can be found in McAlister (2001), Turner *et al* (2001), Sturmann *et al* (2001) and ten Brummelaar *et al* (2001).

Other important surveys—using speckle techniques—have continued the observation of double stars. Recent reports of the Rochester Institute of Technology (RIT) survey can be found in Horch *et al* (2000) and Horch *et al* (2001b). Another important result from this group is related with the magnitude differences for about 130 pairs (Horch *et al* 2001a). A summary of the last 4 years of activity has been presented by Robinson *et al* (2001) while the new camera—called RYTSI—designed by the group is described in Horch *et al* (2001c). Results from the Pic du Midi observatory group, obtained with the Pupil Interferometry Speckle and Coronograph (PISCO) system (Prieur *et al* 1998), have been published by Scardia *et al* (2000) and Prieur *et al* (2001). On the other hand, angular separations, position angles as well as magnitude differences for 606 systems—using a 'regular' CCD camera—have been reported by Gili and Bonneau (2001) and by Lampens *et al* (2001).

Mason *et al* (2000) have re-analysed the information contained in Tycho-2 in attempt to provide basic data for double stars. Another revision and re-reduction of the Tycho-2 by Fabricius *et al* (2002) has resulted in the discovery of over 13 000 new doubles mostly with separation between 0.3 and 1 arcsec. A proper combination with WDS data has permitted the compilation of the Tycho Double Star Catalogue (TDSC) which has more than 100 000 entries. The TDSC is available from the CDS.

Parallaxes

Within the astrometry context, the word parallax is almost always associated with trigonometric parallaxes; that is, a direct way of determing stellar distances. The method is limited to distances less than 100 pc.

The history of the parallax determinations—like that of the astrometric catalogs—is very rich. It is said, for example, that the first attempt to get the parallax of a star was made by Tycho Brahe. Since he could not get any reasonable value he concluded that either (a) the Earth was at rest in the center of the universe or (b) the stars were too far away to make it possible to measure their parallaxes. Since Brahe did not believe the stars could possible be so far away, he chose the first option. This result allowed him to confirm that Copernicus was absolutely wrong in his heliocentric theory of the solar system.

As already mentioned, it was Bessel who—in 1838—detemined the first triginometric parallax of 61 Cygni. By 1890 there were about 30 stars whose parallaxes were known to an accuracy of ±0.05 arcsec (Hoffleit 1992).

By the end of the 19th century—with the adoption of the photographic plate as a detector— the determination of trigonometric parallaxes became a standard research program at some of the most important observatories. In this sense, in 1903, Frank Schlesinger—known as 'the father of modern astrometry' (Hoffleit 1992)—started at the Yerkes Observatory one of the outstanding projects of those days (see Schlesinger 1910). Other institutions such as McCormick, Allegheny, Sproul, Greenwich, Cape, Boschha and Stockholm soon initiated similar projects while Lick Observatory and the USNO Flagstaff Station

Dirac House, Temple Back, Bristol, BS21 6BE, UK

started later using their reflecting telescope, and both extended the determinations to fainter stars.

Most of the work on the determination of trigonometric parallaxes during the photographic era was summarized in the different editions of the General Catalogue of Trigonometric Parallaxes—better known as the Yale Parallax Catalogue (YPC). The first edition of the series was prepared by Schlesinger (1924) and Schlesinger and Jenkins (1935). The third edition was published by Jenkins (1952), followed by her 1963 supplement. The fourth edition of the YPC, the last one of the series, was prepared by van Altena *et al* (1995). It lists trigonometric parallaxes for 8112 stars including photographic as well as CCD determinations.

Once the CCD became available for scientific use, different programs aimed at the determination of trigonometric parallaxes were started. Two of the first reports using CCD techniques are those by Monet (1981) and Monet and Dahn (1983). Fortunately, trigonometric parallax determinations were also made in the southern hemisphere during the early stage of the CCD technique era (see Anguita and Ruiz 1988).

Today, because of the current need of astronomy in surveying and cataloging the solar neighborhood, nearby stars have gained a new interest and so new distances are being determined. From detailed studies of single stars to hemispheric surveys, new results are published almost every year. Among the single-star results we can mention new insights about Proxima Centauri (our nearest neighbor, discovered by R. Innes in 1915) and Barnard's Star by Benedict *et al* (1999); even some evidence for a companion to Proxima Centauri has been mentioned (see Schultz *et al* 1998). Also in the single-star category, it is worth mentioning that a field star that may be the nearest M9 dwarf to the Sun has been identified (Deacon and Hambl 2001). Probably one of the most important results (mainly for the consequences it will have) is the determination of the absolute parallax and relative proper motion of RR Lyrae, a distance scale calibrator, by Benedict *et al* (2002).

The different searches for nearby stars have also reported new results. Among them a survey aimed at the identification of brown dwarfs within 8 pc of the Sun (Hinz *et al* 2002) has revealed no new stellar companions at wide separations; this program is making use of already existing first-epoch images which are combined with new J-band observations.

A search oriented to finding the youngest and nearest (d<60 pc) stars to Earth (using x-ray information as well as astrometric data from Hipparcos and Tycho) is under way by Song *et al* (2001). The final goal of the project is the detection of giant planets. The observations are being carried out from Lick observatory for the northen targets and from Siding Spring Observatory in the south.

A detailed analysis of the Automatic Plate Measuring (APM) measurements of the UK Schmidt Telescope plates by Scholz *et al* (2002) has resulted in the discovery of previously unknown bright ($12<R<15$) high proper motion stars; among them, there are some nearby (d<25 pc) stars.

In the southern hemisphere the Research Consortium on Nearby Stars (RECONS) is engaged in the discovery of new solar neighbors. A large parallax determination program being carried out at CTIO (CTIO Parallax Investigation, CTIOPI) has revealed several nearby stars; one of them is located at 5.5 pc (see Henry *et al* 2001, Jao *et al* 2001). An astrometric survey of companions to nearby stars, with observing telescopes to be located in both hemispheres, is under consideration (Kaplan *et al* 2001).

While in the past most of the parallaxes were determined by ground-based telescopes, the largest number of today's parallaxes are being determined by space satellites. Hipparcos provided almost 120 000 determinations at the accuracy level of 1 mas and SIM and GAIA are expected to furnish a much larger body of data (including parallaxes). In this sense, GAIA for instance will provide astrometric data at the 10 mas level accuracy at V=15 (Torra *et al* 2001) and accurate positions and radial velocities for as much as 1% of the stellar population of the Galaxy (Perryman *et al* 2001). It is obvious that the future of stellar parallaxes—and astrometry in general—looks very promising.

Other projects

Now that CCDs have became the standard detectors for astronomy, it is probably time to change the old classification of astronomical instruments. The most striking case is with meridian circles (MCs). From their first use in astronomy until some years ago, stars were observed by eye (one at a time) when they crossed the meridian. The next step in the development of observing techniques was to replace the human eye by photomultiplier tubes. Now that CCDs have been attached to most of the MCs around the world, the observing procedure has been replaced by the drift scanning mode. This approach allows one to obtain strips from a few minutes up to some hours long in right ascension (Muiños 2002) by some 10–20 arcmin (depending on the size and type of CCD chip) in declination. This data set could easily be compared with that from a normal astrographic telescope. The observations are then reduced using any reference catalog.

Also, some MCs have been engaged in the observation of objects that were traditionally observed by astrograph-type telescopes: minor planets (probably this could be interpreted as a 'return to the roots' since Ceres was discovered by Piazzi observing with an MC). Among these observations we can mention the ones included in

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

the different Carlsberg Meridian Circle Catalogues or those observed by the San Fernando Automatic Meridian Circle—located in San Juan, Argentina, since 1996. Probably the most comprehensive report in this sense is the one by Stone (2000) which includes more than 56 000 positions (in the ICRF) for 1940 asteroids.

The Bordeaux Automated Meridian Circle has just released the M2000 catalog (Rapaport *et al* 2001), which lists over two million stars down to the magnitude limit 16.3. The declination band observed is coincident with the Carte du Ciel observed at Bordeaux. The median internal standard error in position is on the order of 35 mas, while an external comparison with Hipparcos and Tycho-2 catalogs yields an estimate better than 40 mas.

The San Fernando Automated Meridian Circle (equipped with a CCD since December 1999) is engaged in the observation of part of the southern sky to a limit around 16th *V* magnitude. The project is to observe from +3° to –60°. Until now approximately 30% has been completed. The strips (ranging from 20 min up to 3 h long in right ascension by 18 arcmin in declination) are being reduced using Tycho-2 as a reference frame (Muiños and Mallamaci 2002). The observations are expected to be finished sometime during 2005.

The MC of the Abrahão de Moraes Observatory (near Valinhos, Brazil) has been involved in miscellaneous projects. Among them, it is important to mention the extension of the ICRF down to the 15th *V* magnitude (Camargo *et al* 2001). This project includes more than 44 000 stars located around some extragalactic radio sources. This instrument has also been used in the determination of positions for proper motion determination in southern star-forming regions (Teixeira *et al* 2000).

Another important catalog completed during 2000 was prepared at the Nikolaev Astronomical Observatory. The observations were made with the axial meridian circle (AMC). The catalog—available from the web—lists over 14 000 stars and was reduced using USNO-A2.0 as a reference frame. The AMC was put in operation in 1995 (see Pinigin *et al* 1995) and since then it has been involved in observations for different projects (see Kovalchuk *et al* 1997, and Tang *et al* 2000).

Astrolabes have also taken part in many surveys. Over the last 20–25 years a number of improvements in the instruments have been introduced, one example being the Photoelectric Astrolabe II (PA II) developed in China (Luo and Li 1986). Recent results obtained with this new instrument have been published by Manrique *et al* (1999). Other smaller astrometric compilations—using photoelectric astrolabes—have been reported by Hui and Rui (2002) and Martin *et al* (1999). Other surveys, although astrometric in their scope, were actually designed and oriented to improve astrometric parameters of astrophysical objects. López and Girard (1990), for example, improved the positions of over 1000 variable stars. For this project, the authors measured the first-epoch plates of the SPM.

Another project aimed at the improvement of positions and proper motions for variable stars is the Astrometric Catalogue of Variable Stars (ACVS) by Gulyaev and Ashimbaeva (1997). For this study, the authors took the stars listed in the GCVS and the NSV and checked them against those in the 4 Million Catalogue (Gulyaev and Nesterov 1992). Using the finding charts recommended by the GCVS and NSV approximately 21 500 positive cross-identifications were made.

The SDSS (Gunn *et al* 1998) is a large-scale project designed to produce optical photometry and positions for stars down to magnitude 22 in approximately one-quarter of the sky centered on the north galactic cap. In addition, spectra of about one million galaxies, 100 000 quasars and 50 000 stars will be obtained. This 'non-astrometric' survey should produce an enormous quantity of high-quality positions, which, when compared with the first epoch of the POSS, will also result in proper motions. Observations for this project started in 1999 and are projected to last for 5 years.

Besides the optical wavelength projects mentioned in the previous paragraph, some radio-wavelength-based proposals are also making an important contribution to astrometry. Among them, one such proposal, very important because of its global scope, is VERA (VLBI Exploration of Radio Astrometry), which is sponsored by the National Astronomical Observatory of Japan and a group of Japanese universities. The project is aimed at the determination of positions, parallaxes and proper motions of maser sources in the whole Galaxy (see Honma *et al* 2000).

The new millennium

Astronomy in general and astrometry in particular are being favored with the large databases currently in use and those to come in the very near future. This new way of doing astrometry or extracting data for re-analysis includes the use of facilities such as Aladin Sky Atlas (CDS), Astrovirtel, Astrogrid (the UK Virtual Observatory), the SuperCOSMOS Sky Survey or the announced Astrophysical Virtual Observatory (AVO) and the National Virtual Observatory (NVO), among others. The enormous power of these tools—when fully available for public and general use—will allow the handling of different very large databases. Some of the facilities—such as VizieR or SIMBAD—also permit the visualization of all the data (coordinates, magnitude, proper motion, etc.) stored for a given object.

A number of sources will drastically change the way the new astrometric surveys will be performed in the years to come. Among them are the already existing means to extract images (frames) from the digitization of the major photographic surveys (POSS I, POSS II, etc.)—

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

known as Digitized Sky Survey (DSS)—added to the new 'bank of images' such as EIS, the MISAO project, or the Maria Mitchel Observatory (MMO). Another alternative place for images obtained from the digitization of major photographic surveys is the USNO Flagstaff Station (see Levine and Monet 2000). With all this material at the reach of our fingertips, through the web, it will not always be necessary really to have telescopes (big or small) to undertake outstanding astrometrically-oriented research programs. A number of projects, making use of these new possibilities, are currently underway.

Today the DSS has proved to be one of the most extensive bank of images in use. From the confirmation of supernovas (Evans *et al* 2001) to the identification of millions of galaxies (Paturel *et al* 2000), the DSS allows one to undertake almost any project. As an astrometric example of this possibility, we can mention the improvement of positions of ICRF sources (Da Silva Neto *et al* 2000) and almost three thousand objects listed in the Second Byurakan Survey of Blue Compact Galaxies (Bicay *et al* 2000). Also, the combination of DSS frames of different epochs or the blinking between DSS images with those from other surveys (such as the ones available in the MISAO image bank or those from SkyMorph) allows the identification of high proper motion stars (see Scholz *et al* 2001). Another possible way of locating 'missing' high proper motion stars is the combination of different surveys; a project using this approach is being developed by Gould and Salim (2001).

However, not only stellar objects can be included in the search of database compilations; non-stellar objects—such as minor planets and comets—are also being considered and a number of precovery positions have been submitted to the MPC, thus improving the determination of orbital parameters (for a detailed project in this sense see Boattini *et al* 2001). In addition, those frames obtained by some of the most important minor planets (NEOs in particular) searches, such as LINEAR, NEAT and LONEOS, are also appropriate for use in, for example, proper motion determinations. These frames are easily accessible through the SkyMorph facilities.

There are also a number of research programs making use of the already existing high-quality astrometric catalogs mainly Hipparcos and Tycho-2. These databases have been used in—among other projects—the study of proper motions of open clusters (Dias *et al* 2001) and in a star-forming complex (Belikov *et al* 2002). In some other cases, the high accuracy of these compilations (mainly Tycho-2) has allowed the determination of 'astrometric radial velocities' for stellar members of open clusters (see Masden *et al* 2002). The articles, as well as the web addresses, mentioned in this section are only a small (and far from complete) example of what could be done by using the material available in the major data centers. However, the potentialities of these new tools have not yet been exploited in all of their capabilities; once this happens, there will be a big impact in the way astrometry will carry out the new astrometric surveys from that moment on.

These new possibilities, plus the even larger body of data to be furnished by the coming space missions (GAIA, SIM, etc.) planned for the years ahead, will change the way the astrometric surveys of the near future will be done. They will be much easier and—at the same time—much more complicated to develop: easy because simply with the access to the web it will be possible to extract many megabytes of information; complicated, because it will require not only larger computer facilities to handle that amount of data properly but also (and probably more important), new concepts in computer technology (see Longo *et al* 2001). When this happens, astrometry will have the opportunity to grow and to expand into new and unexpected domains.

However, of course, not only astrometry will change; in fact, the most significant change will be in the way we see and understand the universe around us.

Appendix

Summary of Acronyms

A large number of acronyms are currently being used to refer to the astrometric surveys, instruments and institutions engaged in astrometric projects. Below is a summary of acronyms mentioned in the present work, and others found elsewhere in the current relevant literature.

2MASS	Two-Micron All Sky Survey
AC	Astrographic Catalogue
ACRS	Astrographic Catalogue Reference Stars
ACT	Astrographic Catalogue and Tycho
ACVS	Astrometric Catalogue of Variable Stars
AGK	Astronomisches Gesselschaft Katalog
APS	Automated Plate Scanner
AVO	Astrophysical Virtual Observatory
BD	Bonner Durchmusterung
CAMC	Carlsberg Automatic Meridian Circle
CCD	Charge-coupled device
CDS	Centre de données astronomiques de Strasbourg
CHARA	Center for High Angular Resolution Astronomy
CoD	Córdoba Durchmusterung
CPC2	Second Cape Photographic Catalogue
CPD	Cape Photographic
CTIO	Cerro Tololo Inter-American Observatory
CTIOPI	CTIO Parallax Investigation
DENIS	Deep Near-Infrared Survey
DSS	Digitized Sky Survey
EIS	ESO Imaging Survey
ESA	European Space Agency
ESO	Europen Southern Observatory

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

FAME	Full-Sky Astrometric Mapping Explorer
FK	Fundamental Katalogs
FOCAT-S	Photographic Catalogue—South
GAIA	Global Astrometric Interferometer for Astrophysics
GC	General Catalogue
GCVS	General Catalogue of Variable Stars
GSC	Guide Star Catalogue
HDEC	Henry Draper Extension Charts
HDF	Hubble Deep Field
HIPPARCOS	High Precision Parallax Collecting Satellite
HST	Hubble Space Telescope

Astrometry

The branch of astronomy dealing with the precise measurement of the position of astronomical bodies. Many problems of astronomy require accurate observations of stellar positions. Positions of the brighter stars can be measured very accurately in the equatorial system. Fainter stars are measured using photographic plates or some other imaging device (e.g. a charge-coupled device, or CCD) with respect to the brighter stars. The entire stellar group can then be referred to the positions of known external galaxies, which are far enough away to define an essentially fixed system. Over relatively short periods of time both the bright and faint stars are affected by galactic rotation and by their own motions through the Galaxy. The most precise stellar positions to date have been obtained by the Hippacos satellite.

Astrometry with Hubble Space Telescope

In 1990 NASA launched the HUBBLE SPACE TELESCOPE. In addition to cameras and spectrographs usable from the far ultraviolet to the near-infrared, the observatory contains three white-light INTERFEROMETERS. As part of engineering and science support their primary task was telescope guiding; to position and hold science targets within the science instrument apertures with tolerances approaching 0.1″, equivalent to 100 milliseconds of arc (100 mas). Pointing and tracking requires two such fine guidance sensors (FGS), leaving the third free for ASTROMETRY.

The design goal for astrometry with an FGS was 3 mas precision over the entire field of regard. When designed and built in the early 1980s, The FGS represented an order of magnitude improvement over existing ground-based techniques. HST launch delays provided sufficient time for ground-based techniques to equal and surpass this goal. Thus, the post-launch goal was redefined. This goal, 1 mas precision small-field astrometry, has been achieved, but not without significant challenges.

An HST FGS will remain a competitive astrometric tool for faint targets in crowded fields and for faint small-separation binaries, until the advent of large-aperture ground-based and longer-baseline space-based interferometers (see also ASTROMETRY: TELESCOPES AND TECHNIQUES).

This article describes the science that can be done with the FGS and presents some recent science results. We outline how these data are modeled, acquired and calibrated. We next show how the astrometer, FGS 3, works as an interferometer. Finally, we present a guide to the literature that provides additional detail for each item discussed in this article.

Astrometry with 1 mas precision is obtainable with the HST wide field planetary camera. The techniques are similar to those used in ground-based CCD astrometry and should be discussed separately.

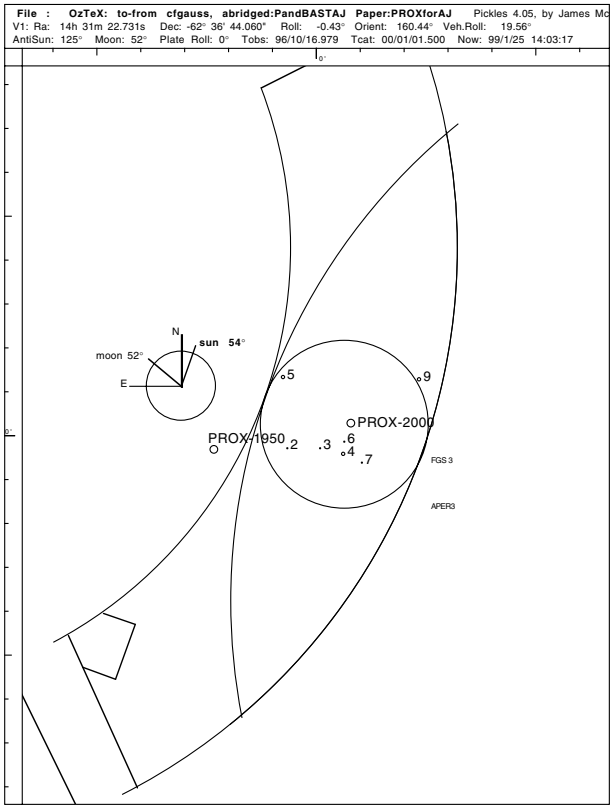

Figure 1. Field of regard of FGS 3 on the sky at the location of the planet search target, Proxima Centauri, on 16 October 1996. The position of Proxima Centauri at two epochs is plotted. Also shown are the reference stars, relative to which parallax and proper motion are obtained. Tick marks are separated by 1 arcminute.

The choice of science targets

The choice of HST astrometry science targets is rightly determined by what can be done from the ground. The unique capabilities of HST must remain reserved for projects demanding them. In this section we summarize the strengths of HST astrometry, pointing out a few examples of the kinds of objects for which HST and the FGS are ideally suited. Since the FGS interferometer offers two observational modes, fringe scanning and fringe tracking, we divide the remainder of this article by mode at each step.

Fringe scanning: using HST for binary star astrometry

Four characteristics of a high-resolution (<1″) observing technique must be considered when attempting to resolve a target BINARY STAR: the source brightness limit, the resolving capability, the astrometric accuracy and the magnitude difference between the components that can be observed. Although all four parameters are interdependent, we provide current limits for each characteristic separately in order to illustrate the efficacy of HST FGS 3 as an astrometric instrument.

For binary stars HST FGS 3 observations provide results currently unachievable with ground-based techniques. HST FGS 3 is accurate to 1–3 mas at a resolution limit of 15 mas for magnitude differences less than 2 mag. It can effectively observe targets to at least $V \sim 15$. At component separations greater than 200 mas, it can bridge brightness differences of at least $\Delta V = 4$ mag, as demonstrated by the detection of Gliese 623B.

Future developments in ground-based interferometers (see INTERFEROMETRY: GROUND) should improve the accuracy of astrometric measurements and provide better resolution, but will still be limited to relatively bright targets and moderate magnitude differences. HST FGS 3 is the only high-resolution instrument currently available that (a) can provide high-precision astrometry for very close binaries, (b) allows relatively faint targets to be observed, and (c) can bridge at least moderately large magnitude differences between the components in a binary system.

Fringe tracking: using HST to obtain parallaxes

In the absence of distance, astrophysics lacks precision. Our demonstrated measurement precision for PARALLAXES is 0.5 mas or better, given six epochs of observation at maximum parallax factor. Often a parallax target is unmeasurable because reference stars are not located within the field of view of the measuring device; this is especially true for small-format (typically several square arcmin) CCD cameras. An FGS provides a large field of regard (figure 1), shaped somewhat like a pickle. This shape comes from the the pick-off mirror (figure 5) in the HST focal plane. Parallax observations are generally spaced by six months, during which time, due to HST solar array illumination constraints, the FGS field of view rotates by 180°. The lens-shaped region (figure 6) in common to the two extreme orientations provides a relatively large field with short axis = 3.5′ and long axis = 14′.

FGS 3 has a large dynamic range, able to obtain fringe tracking position measures for stars in the magnitude range $4 \leq V \leq 17$. This large dynamic range is provided by a neutral density filter that reduces the magnitude of bright stars by 5 mag. The unfiltered range is $8.5 \leq V \leq 17$.

HST can obtain precise parallaxes for binaries whose components are separated $0.03'' < \rho < 1.0''$. Nearly simultaneous fringe scanning and tracking measurements provide the component positions relative to reference stars, essential in determining the center of mass of a system, and thus individual component masses.

Lastly there is timeliness of result. One no longer need wait three to six years for the parallax of astrophysically interesting objects. The distance to a sufficiently interesting and important object can be obtained on the same time scale as other astrophysical information. If an object or class of objects is interesting now, a theory can be tested now.

Science results

Science targets have included nearby stars used as probes for an extrasolar planet search; stars whose astrophysics would be greatly aided by accurate distances; low-mass binary stars to define the mass–luminosity relation for the lower main sequence; members of the Hyades cluster, key to the distance scale; extragalactic objects (QSO) to provide an inertial reference frame for Hipparcos; and the epitome of crowded fields, an extragalactic cluster, R136 in the Large Magellanic Cloud.

Once again we divide by technique, discussing representative results from first fringe scanning then fringe tracking.

Fringe scanning and binary stars

Fringe scanning science depends on deconvolution and the assumption that all objects in the field are point sources. For a recent science result we turn to the low-mass binary Wolf 1062 = Gl 748, observed in support of a lower main sequence mass–luminosity project. Figure 2 presents fringe scans of this binary along the two orthogonal axes of FGS 3. Since each observed fringe is a linear superposition of two fringes (one for each component star in the binary), it is modeled with two identical single star fringes. Their placement along the axis and relative amplitudes provide separation and brightness differences. Relative separation along the two axes provides position angle information. Figure 3 shows all the measured separations and position angles on the best-fit orbit. The mean absolute difference between the observed and computed separations is only 1.1 mas, and only 0.77° in the position angle. Residual vectors for all data points are drawn, but are smaller than the points. Perhaps it is even more impressive to realize that the box illustrated is only 0.6″ in size, so that good seeing from the ground would result in a stellar image the size of the entire figure.

A combination of fringe scanning and fringe tracking observations for the low-mass binary L722-22, has yielded a relative parallax $\pi = 0.1656'' \pm 0.0008''$ and component masses of 0.179 and 0.112 $M_{\odot}$ with formal random errors for the mass as low as 1.5%.

Fringe tracking: positions in a reference frame

Fringe tracking science is primarily that of relating the position of a target to positions of stars defining a reference frame. Here we discuss a Hyades parallax program and a fundamental astrometry project involving HIPPARCOS.

Trigonometric parallax observations were obtained for seven Hyades members in six fields of view. These have been analysed along with their proper motions to determine the distance to the cluster. Formal uncertainties on individual parallaxes average 1 mas. This relatively large error is due both to poor spatial distribution and the small number of reference stars in each field. Knowledge of the convergent point and mean proper motion of the Hyades is critical to the derivation of the distance to the center of the cluster. Depending on the choice of the proper-motion system, the derived cluster center distance varies by 9%. Therefore, a full utilization of the HST FGS parallaxes awaits the establishment of an accurate and consistent proper-motion system.

Observations of separations of Hipparcos stars from extragalactic objects have been made to determine the rotation of the Hipparcos instrumental system with respect to the ICRS-VLBI reference frame. A determination from 78 observations yields accuracies of the order of 2 mas rms in the coordinate rotational offsets near the mean epoch of the HST observations and 2 mas yr^{-1} in the coordinate rotation rates. The main contributing sources of error are HST measurement errors and proper motion errors introduced by the three year time difference between the mean Hipparcos and HST observational epochs.

Data modeling

Our two examples are a binary star for fringe scanning and a parallax field for fringe tracking.

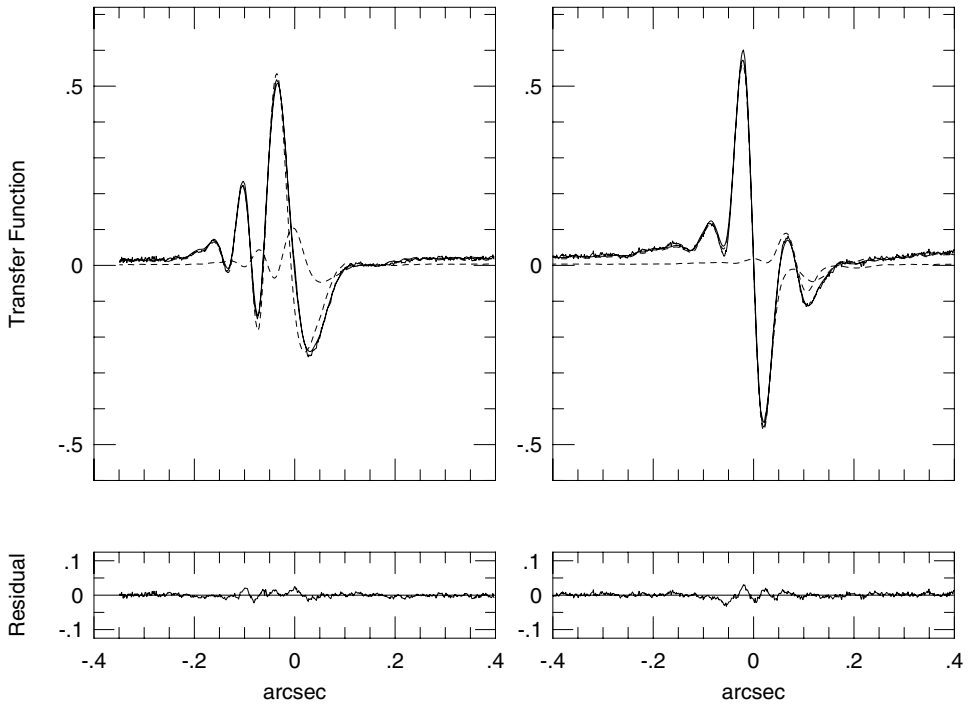

Figure 2. Analysis of the 1995.5712 observation of Wolf 1062. The computed (smoothed full) curves in X (left) and Y (right) represent best-fitting linear superpositions of two single-star fringes (dashed curves). The relative displacements of the single-star curves are $0.0329'' \pm 0.0003''$ and $0.0862'' \pm 0.0002''$ along FGS X and Y respectively. They yield separation and position angle, while the relative amplitudes of the single-star curves yield a magnitude difference for the binary components. The systematic trends in the curve-fitting residuals (bottom panels) are due to imperfect single-star calibrations. Their effect upon the astrometry and photometry of the Wolf 1062 components is negligible.

Fringe scanning

We consider a binary star as the simplest object requiring fringe scanning.

We assume that the fringe produced by a binary star is a linear superposition of the fringes produced by two single stars. The interferometer response to an actual binary star is shown in figure 2. If $F(x)$ is the fringe produced by a single star on the x-axis, a binary star should be described by

$$D(x) = A \times F(x + z_x) + B \times F(x + z_x + S_x) \qquad (1)$$

where A and B are the relative intensities of the two components (constraining $A + B = 1$). The zero point offset, z_x, and a component separation, S_x, complete the model, there being a similar expression for the fringe produced along the y-axis. S_x and S_y yield the binary separation, and, once transformed to equatorial coordinates, the position angle. We obtain the magnitude difference from

$$\Delta m = -2.5 \times \log(A/B). \qquad (2)$$

If a binary is observed in fringe tracking mode, the FGS will lock on an erroneous zero-crossing position which is generated by two closely overlapping s-curves. A fringe scanning mode observation gives relative positions of the two components. One can determine the relative positions with an accuracy and precision of 1 mas, once the fringes from the two stars are deconvolved.

Fringe tracking

We consider a typical parallax target and associated reference stars as an example of fringe tracking. The primary science target is ideally surrounded by five to ten other stars used as a reference frame relative to which we determine position and motion.

Fringe tracking astrometry is generally a two-step process. We first determine the characteristics of the reference frame. One of the epochs of observation is chosen as the constraint plate. From these data we determine the scale and rotation relative to the constraint plate for each observation set within a single orbit. Since for many of our targets the observation sets span over two years, we also include the effects of reference star parallax (π) and proper motion (μ)

$$\xi = ax + by + c - (P_x * \pi + \mu_x * t) \qquad (3)$$

$$\eta = dx + ey + f - (P_y * \pi + \mu_y * t). \qquad (4)$$

The orientation relative to the celestial sphere is obtained from ground-based astrometry. Uncertainties in the field orientations are generally $0.03^\circ < \epsilon_\theta < 0.09^\circ$.

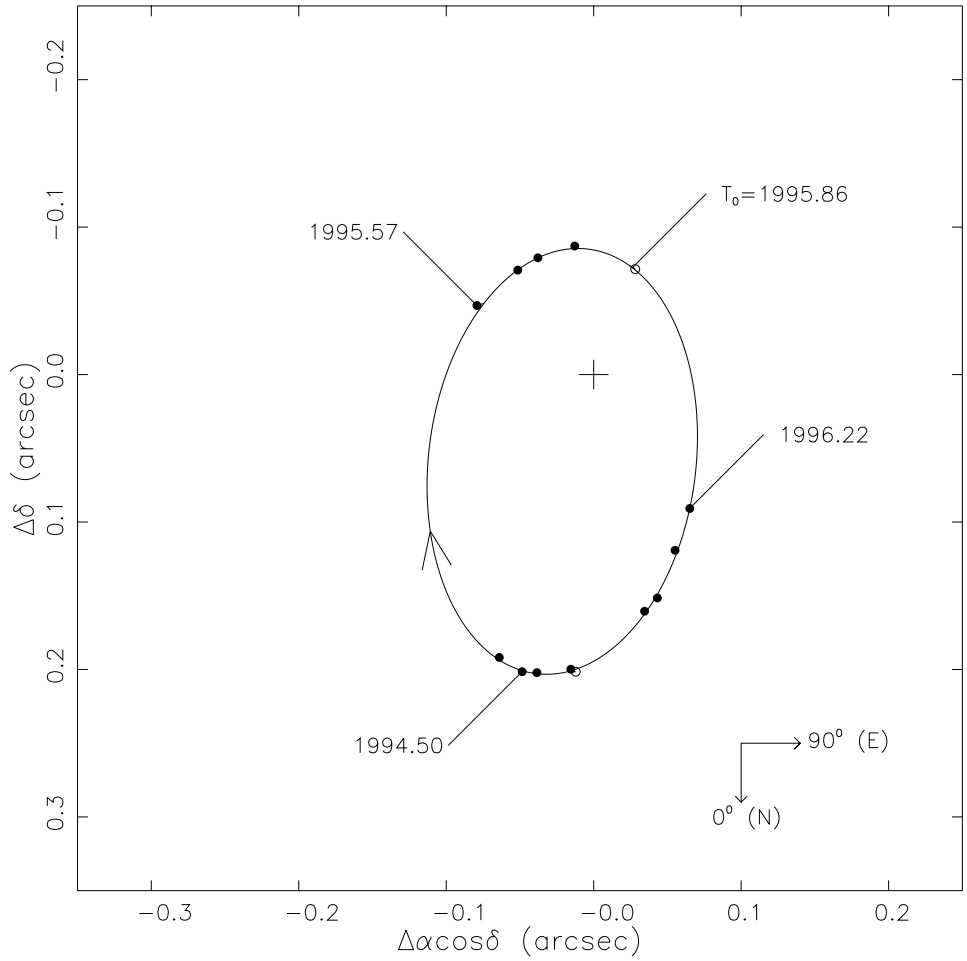

Figure 3. HST FGS3 measurements of Wolf 1062AB and the orbital path predicted by the derived elements are shown. Three epochs of observation and the time of periastron are labelled. Residual vectors for all data points are plotted, but are smaller than the points themselves.

We obtain the parallax factors P_x and P_y from a JPL Earth orbit predictor. Finally, for a rich-enough reference field ($n >$ four stars) we constrain $\Sigma\mu = 0$ and $\Sigma\pi = 0$ for the entire reference frame.

The second step consists of applying the plate constants to the measurements of the science target. Plate coefficients $a, b, ..., f$ are applied as constants, while we solve for the science target π and μ in the above equations.

The astrometer

The design

FGS 3 is an interferometer. Interference takes place in a prism that has been sliced in half, had a quarter-wave retarding coating applied, and then reassembled. Figure 4 shows one of these Koester prisms. Most of the FGS consists of supporting optics used to feed the Koester prisms (figure 5). In particular the star selectors walk the 5″ instantaneous field of view throughout the interferometer field of regard shown in figure 1. The output of each face (face A and face B) is measured by a PMT. These signals are combined

$$S = \frac{A - B}{A + B} \tag{5}$$

to form a signal, S, that is zero for waves exactly vertically incident on the Koester prism's front face. Tilting the wavefront back and forth (equivalent to pointing the telescope slightly off, then on target, then slightly off to the other side) generates the fringe pattern seen in figure 2. A perfect instrument would generate a perfectly symmetric fringe pattern. The significant spherical aberration of the as-built HST primary mirror, in the presence of internal FGS misalignments, produces a signature in the fringe which mimics coma. Coma causes decreased modulation and multiple peaks and valleys in a fringe. FGS 3 produces the least complicated fringes over the widest area within the field of regard.

A replacement FGS installed in 1997 contains an articulated fold-flat mirror that removes most of the internal misalignments. This FGS (FGS 1r) produces

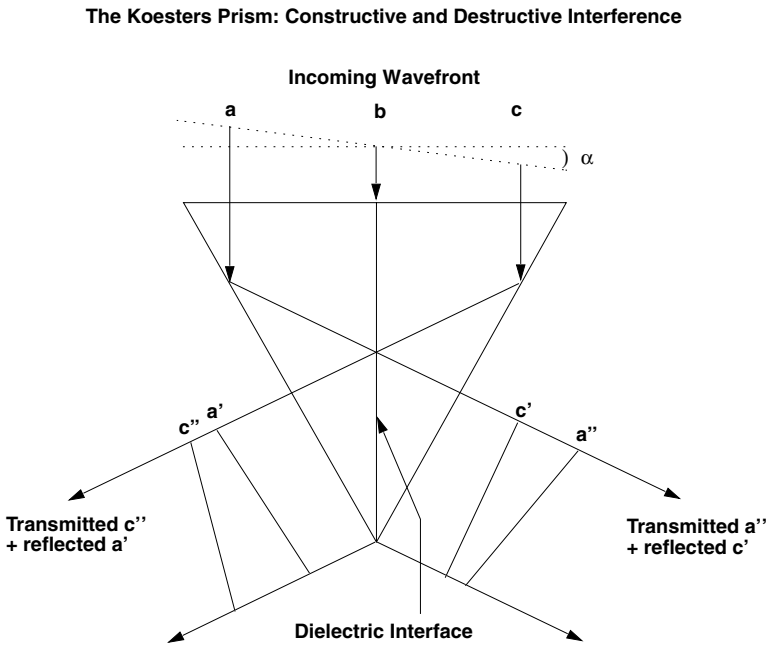

Figure 4. The heart of the FGS interferometer, the Koester prism.

nearly perfect fringes and should at a minimum yield superior binary star results. FGS 3 will remain in service until FGS 1r is fully calibrated in 2000.

FGS operating modes

We discuss strategies for obtaining the highest quality data possible. Our goal, 1 mas precision small-field astrometry, has been achieved, but not without significant challenges. These included a mechanically noisy on-orbit environment, the self-calibration of FGS 3, and significant temporal changes in our instrument. Solutions include a denser set of drift check stars for each science observation, fine-tuning exposure times, overlapping field observations and analyses for calibration, and a continuing series of trend-monitoring observations.

The single greatest contributor to data quality is to treat all data aquired in the same orbit as a unit observation, e.g. a 'plate'.

Fringe scanning

The target is placed in the center of the 'pickle' and the star selectors are commanded to move the instantaneous field of view across the target star image. This action produces a fringe. In practice 10–30 scans are obtained in a reciprocating pattern forwards and back across the star. The final fringe results from a reversal, shift and add process. We have evidence that over the span of an orbit the positions reported by FGS 1 and FGS 2 for the guide stars change. This results in a drift-like motion of FGS 3, the astrometer. Drift can exceed 30 mas over the span of 36 min. The x and y drift rates are generally dissimilar and the drift is not of constant rate. However, since a single scan across a science target requires about 1 min, the drift per scan is reduced to less than 1 mas. The reciprocating data acquisition strategy is very nearly self-compensating for drift.

Fringe tracking

For fringe tracking, onboard electronics locate the zero crossing between the highest positive and lowest negative fringe peak (see figure 2). The position of this zero crossing is determined at a 40 Hz rate during an observation time ranging between $10 < t < 300$ s. The median of >2400 zero crossings provides a robust position estimate. The star selectors are used to move the instantaneous field of

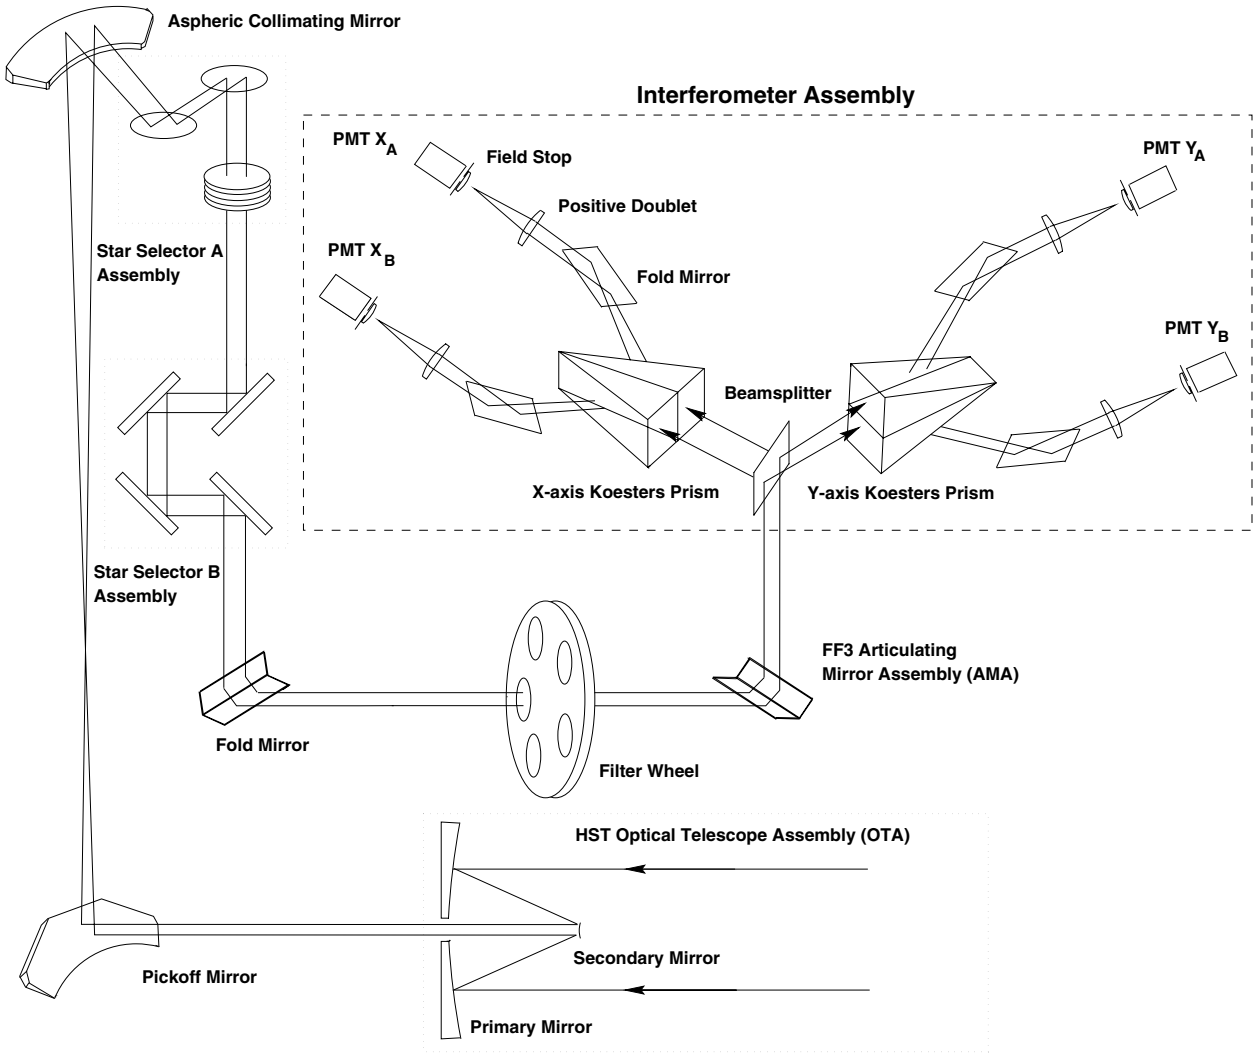

Figure 5. The optical layout of a fine guidance sensor.

view from one star to the next in the FGS field of regard shown in figure 1.

Drift is correctable, but imposes additional overhead, reducing the time available within an orbit to observe the science target. An astrometric observation set must contain visits to one or more reference stars, multiple times during each observation sequence. Presuming no motion intrinsic to all reference and science target stars over a span of 40 min, one determines drift and corrects the reference frame and target star for this drift. As a result we reduce the error budget contribution from drift to less than 1 mas. In figure 1, the science target might be observed three times during an observing session (single orbit) and each reference star twice.

Astrometric calibration

The calibration of the fringe scanning mode has as its goal the determination of separation and magnitude differences between components of binary stars. As discussed earlier, all fringe scanning targets are observed near the pickle center. In contrast fringe tracking takes place over the entire field of regard. Calibration requirements for these two modes of operation are quite different.

Fringe scanning calibration

The most fundamental calibration for any astrometric instrument is to determine the scale in units of the celestial sphere. The FGS scale comes from measurements of several calibration binary stars frequently observed by speckle interferometry with 4 m class telescopes. On the basis of these speckle measures, extremely well-determined orbital elements have been obtained. These binary star orbits yield, for any date of HST FGS observation, accurate angular separations of the binary, and hence the scale.

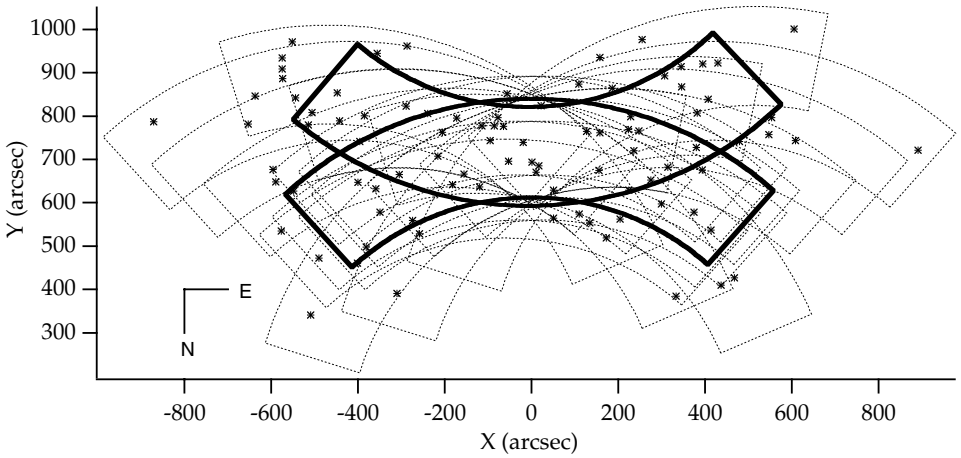

Figure 6. The fringe tracking self-calibration of FGS 3. Stars in the cluster M35 were observed at 19 different pointings and rolls of HST. The pickle-shaped regions denote the total FGS field of regard. The black dots are stars within the cluster M35. The lens-shaped area in the middle shows the field of view for parallax studies.

Secondary calibration consists of the development of a library of suitable single star fringe templates. This library is required since fringe morphology weakly depends on star color. From a library of templates the required number (one for each component of a binary or multiple star system) are chosen and fitted to the binary star fringe using the least-squares algorithm, GaussFit, that allows for errors in both independent and dependent variables.

Fringe tracking calibration

The optical telescope assembly (OTA) of the HST is an aplanatic CASSEGRAIN TELESCOPE of Ritchey–Chrètien design. Our initial problem included mapping and removing optical distortions whose effect on measured positions exceeded 0.5″. There was no existing star field with cataloged 1 mas precision astrometry, our desired performance goal, to use as a fiducial grid. Our solution was to use FGS 3 to calibrate itself. As a result of this activity distortions are reduced to better than 2 mas over much of the FGS 3 field of regard (figure 1). This model is called the optical field angle distortion (OFAD) calibration.

To describe these distortions we have adopted a pre-launch functional form originally developed by the instrument builder, the Perkin-Elmer Corporation. These distortions can be described (and modeled to the level of one millisecond of arc) by the two-dimensional fifth-order polynomials

$$\begin{aligned} x' = {} & a_{00} + a_{10}x + a_{01}y + a_{20}x^2 + a_{02}y^2 + a_{11}xy + a_{30}x(x^2+y^2) \\ & + a_{21}x(x^2-y^2) + a_{12}y(y^2-x^2) + a_{03}y(y^2+x^2) \\ & + a_{50}x(x^2+y^2)^2 + a_{41}y(y^2+x^2)^2 + a_{32}x(x^4-y^4) \\ & + a_{23}y(y^4-x^4) + a_{14}x(x^2-y^2)^2 + a_{05}y(y^2-x^2)^2 \\ y' = {} & b_{00} + b_{10}x + b_{01}y + b_{20}x^2 + b_{02}y^2 + b_{11}xy \\ & + b_{30}x(x^2+y^2) + b_{21}x(x^2-y^2) + b_{12}y((y^2-x^2) \\ & + b_{03}y(y^2+x^2) + b_{50}x(x^2+y^2)^2 + b_{41}y(y^2+x^2)^2 \\ & + b_{32}x((x^4-y^4) + b_{23}y(y^4-x^4) + b_{14}x(x^2-y^2)^2 \\ & + b_{05}y(y^2-x^2)^2 \end{aligned} \tag{6}$$

where x, y are the observed positions within the FGS field of view, x', y' are the corrected positions, and the numerical values of the coefficients a_{ij} and b_{ij} are determined by calibration. Ray-traces were used for the initial estimation of the OFAD. Gravity release, outgassing of graphite-epoxy structures within the FGS, and post-launch adjustment of the HST secondary mirror required that the final determination of the OFAD coefficients a_{ij} and b_{ij} be made by an on-orbit calibration.

M35 was chosen as the calibration field. Since the ground-based positions of our target calibration stars were known only to 23 milliseconds of arc, the positions of the stars were estimated simultaneously with the distortion parameters. This was accomplished during a marathon calibration, executed on 10 January 1993 in FGS 3. The entire 19 orbit sequence is shown in figure 6. GaussFit was used to simultaneously estimate the relative star positions, the pointing and roll of the telescope during each orbit (by quaternions), the magnification of the telescope, the OFAD polynomial coefficients, and four parameters that describe the star selector optics inside the FGS.

Other fringe tracking calibrations

Because each FGS contains refractive elements (Bradley *et al* 1991), it is possible that the position measured for a star could depend on its intrinsic color. Changes in position would depend on star color, but the direction of shift is expected to be constant, relative to the FGS axes. This lateral color shift would be unimportant, as long as target and reference stars have similar color. However, this is certainly not the case for many of the science targets (e.g. very red stars such as Proxima Centauri and Barnard's star).

Finally, to provide the large dynamic range, a neutral-density filter can be placed in front of the Koester prism. As a consequence there will be a small but calibratable shift in position (due to the filter wedge) when comparing the positions of the bright star to the faint reference frame. The shift is constant in direction (relative to FGS 3) and size, since the filter does not rotate within its holder.

Maintaining the fringe tracking calibration

The FGS 3 graphite-epoxy optical bench was predicted to outgas for a period of time after the launch of HST. The outgassing was predicted to change the relative positions of optical components on the optical bench. The result of whatever changes were taking place was a change in scale. The amount of scale change was far too large to be due to true magnification changes in the HST optical assembly. Two of the parameters that descibe the star selector optics cause a scale-like change, if they are allowed to vary with time.

The solution was to revisit the M35 calibration field periodically to monitor these scale-like changes and other slowly varying nonlinearities. Revisits will be required as long as it is desirable to do 1 mas precision astrometry with any FGS. The result of this activity judges the validity of the current OFAD coefficients and provides warning for the need for recalibration. With these data we remove the slowly varying component of the OFAD, so that uncorrected distortions remain below 2 mas for center of FGS 3. The character of these changes is generally monotonic with abrupt jumps in conjunction with HST servicing missions.

Bibliography

Here are pointers to a number of key papers in the development of HST interferometric astrometry, and to some recent results.

A detailed description of the FGS interferometer can be found in:

Astrometry: History

Although the term 'astrometry' was not coined until the 19th century, the business of measuring the position and angular separation of the stars and planets constitutes one of the most ancient occupations of the astronomer. By the time of HIPPARCHUS (*fl* 126 BC) in classical Greece, the measurement of astronomical positions with relation to the 360° circle was already established, while the ancient Babylonians of 1750 BC left non-instrumental observations of the western and eastern elongations of Venus with relation to the Sun, which might be correctly considered as astrometric. From Greek times to the present day, astronomers involved in astrometric work have used instruments employing the 360° scale, and one can follow this technical instrumental development in the article DIVIDED INSTRUMENTS.

By its very nature, astrometry entails establishing and refining physical coordinates in the sky, against which the movements of bodies can be quantified. Hipparchus, Claudius PTOLEMY and other Greeks recognized that the ecliptic provided a natural and fairly obvious fundamental astronomical coordinate system, as the mid-summer and mid-winter altitudes of the Sun produced the solstices, equinoxes and zodiac poles. These zodiac coordinates, moreover, could be related to a different set of coordinates, based on the terrestrial equator (or equatorial) and terrestrial poles; in the time of Ptolemy these were 23º 51' 20" apart and are now 23º 26' 21". The geometrical points in the sky where the ecliptic and the equatorial planes intersect, the equinoxes, form a coordinate of natural origin, and the spring intersection in March was used by Ptolemy and other classical astronomers to delineate the beginning of the stellar day. Over two millennia ago, this point resided in the constellation Aries, giving rise to the term 'FIRST POINT OF ARIES', which is still used today as the zero point in celestial longitude (or right ascension) on astronomical charts. Even in antiquity, however, it was recognized that this first point is not fixed (as, indeed, are few points in the sky, given enough time), but moves back upon itself, or 'precesses'. Ptolemy quantified this precession as 1º every century, although he obtained this amount by rounding up the figures for the first point, which he derived from observations covering about 400 yr up to AD 150. Employing greatly superior instruments, and using them to constantly refine and re-define his figure between 1675 and 1715, JOHN FLAMSTEED in England obtained 1º every 72 yr, or 50" yr^{-1} for the precessional constant, which compares very favorably with the 50.290 966" yr^{-1} accepted today.

The establishment of the first point of Aries, and the quantification of its albeit errant motion around the sky, is one of the fundamental achievements of astrometry, and still lies at the heart of stellar positional measurement, requiring charts and tables to be constructed to a particular 'epoch' in the precessional cycle, such as AD 1900 or AD 2000.

The practical measurement of the exact position of this slowly moving piece of empty space in the sky has been a test of ingenuity over the centuries, for inevitably it is occupied by no specific star. In the 2nd century AD Ptolemy in his *Almagest* described a technique employing the new moon as an intermediary. On or around the day of the spring equinox, in such years as there was a convenient new moon at the equinox, Ptolemy measured the angular distance of the setting Sun from the Moon. Once the Sun was below the horizon, he recommended that the position of the Moon be measured from the adjacent stars when they became visible. From these star positions, it was possible to establish the position of the Sun and determine thereby (from a knowledge of the stars in that region of the sky gained some months before) which bright star was closest to the first point of Aries.

Recognizing that the motion of the Moon could itself be a source of error, during the hour or so that the Sun was declining below the horizon, TYCHO BRAHE in Denmark from 1582 repeated Ptolemy's technique using the much slower-moving planet Venus as an intermediary, and computed for that epoch that the first point of Aries stood 26º 0'" 30" removed from the star α Arietis, which was within 15" of the same value calculated for 1585 by Dreyer in the 1890s. The success of Tycho's astrometric work, and the superior accuracies he achieved when compared with the medieval Arabs such as Ulugh Beigh and Al Sufi, and the ancient Greek astronomers who had been observing a millennium earlier, depended on improvements in technique. These included fundamental innovations in instrument design, sophisticated cross-checking procedures and a growing awareness of atmospheric refraction.

The massive strides that astrometry has made over the last four centuries have followed on from an increasing awareness of the factors recognized as important by Tycho: instrument innovation, refined techniques, and an alertness to potential sources of error. However, astrometry's meteoric development since 1580 has only been in response to the intellectual problems posed in astronomy and cosmology, the first of which was the Copernican hypothesis. It was recognized in the 16th century that if the Earth did indeed move in space, then the angular sizes of the constellation figures should display a slight seasonal variation, as the earth-based observer approached or receded from the June and December positions. Tycho himself attempted to detect such seasonal variations. With the development of the concept of the infinite universe in the 17th century, however, this Copernican stellar parallax was seen as most likely to be detected in the six-monthly angular displacement of first-magnitude stars, such as Sirius,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

working on the assumption that, if all stars were of similar intrinsic brightness, those of the first magnitude were the closest to Earth, and hence should display the largest parallaxes.

The development in the 17th and 18th centuries of superior scale graduations on astronomical quadrants, telescopic sights, micrometers and verniers, and of similar instrumental techniques, was strongly driven by the urge of astronomers to detect this elusive stellar parallax. As the astrometric capacity of the age increased from Tycho Brahe's 1' to Hevelius's 25", and then to Flamsteed's 10", and still no parallax was found, astronomers across Europe realized two things: firstly, the three-dimensional stellar universe must be unbelievably vast and, secondly, any hope of successfully fathoming it must reside in an ongoing improvement in the construction of precision instruments, combined with a parallel development in the refined techniques of their usage. This recognition, moreover, has been the creed of the astrometer for the last four centuries from Tycho's Uraniborg to the European Space Agency's Hipparcos space satellite.

The search for a stellar parallax, while not successfully accomplished until 1838, created such an urgency and an inspiration to astronomers that numerous other discoveries and lines of inquiry were born out of it on the way. It was CHRISTIAAN HUYGENS's recognition in the 1650s that graduated scales were insufficiently refined to detect a parallax, indeed, that led to the beginning of stellar photometry. By attempting to compare the brightness of Sirius with the light emitted from a pinhole-sized area of the solar surface (assuming that the Sun, Sirius and all stars possessed the same intrinsic luminosity), Huygens calculated that Sirius was 27 664 astronomical units distant from the solar system. Huygens's technique encouraged the photo-astrometric studies of Sir John Herschel in 1836, where he calculated that Vega was 40 times brighter than the Sun, and Arcturus 200, and hence correspondingly remote from the solar system. Then in the wake of the successful application of spectroscopy and photography to astrometry in the 1860s, photometry began its independent development as a fundamental tool of astrophysics.

The quest for the stellar parallax was also to lead ROBERT HOOKE (1669), John Flamsteed (1698–1702) and especially JAMES BRADLEY (1727–1728) to the invention and development of the zenith sector (a long-focus telescope hung to point exactly at the zenith) as a way whereby the stellar parallax, now recognised as being no more than a few seconds of arc in extent, might be detected in the atmospheric-refraction-free sky of the zenith. Both Hooke and Flamsteed came up with suspiciously large parallaxes: Hooke made that of the star γ Draconis to be around 27" and Flamsteed that of Polaris 40", although the superior instrumentation and observing procedures of Bradley led to his recognition in 1728 that a 'New Found Motion' of the fixed stars, which was itself the product of the Earth's rotation about the Sun, had an annual displacement of 20.00"–20.25". This was the aberration. Its detection and quantification were a triumph of the refined astrometry of the 18th century and, while still not revealing a parallax, none the less it provided physical proof of the Earth's motion in space. Bradley claimed that his zenith sector was capable of detecting an angle of 0.5", and in 1748 he used the tiny nodding motion of γ Draconis to detect a small periodic change in the inclination of the earth's axis of rotation with regard to the ecliptic.

One of the assumptions implicit within the concept of the infinite universe was the possible independent motion of the stars themselves, especially in the wake of Sir ISAAC NEWTON's theory of universal gravitation after 1687. From time immemorial it had been assumed that the stars were fixed in their places, although in 1718 EDMOND HALLEY published a paper which showed that the first-magnitude stars Aldebaran (Palilicium), Sirius, and Arcturus had displayed an independent or 'proper motion' *vis-à-vis* their adjacent, dimmer stars. This had been the product of an ingenious historical investigation, in which Halley had detected a systematic displacement in latitude of these stars, as recorded by Hipparchus, Ptolemy, Tycho and contemporary astronomers. Indeed, he calculated that Sirius had changed its longitudinal position by 2' in the 120 yr since Tycho. The implication was not only that these stars might be moving in space but that our observing position in the solar system might be moving as well. William Herschel in 1783 was the first to use proper motions to derive the solar apex, the point in the sky towards which the solar system is moving (see HERSCHEL FAMILY).

It says something about the rapid advances in astrometry and its instrumentation that no fewer than three stellar parallaxes were found between 1838 and 1840, by astronomers using three different techniques of observation. None of these parallaxes, moreover, would have been measured but for the discovery and increasingly accurate quantification of stellar proper motions, for it was the large proper motions displayed by 61 Cygni (5".2 yr^{-1}) and α Centauri (3".7) that suggested their relative closeness to the solar system and hence their suitability for parallax measurement. Although displaying a much smaller (yet clear) proper motion, Vega (α Lyrae) was also considered as a suitable candidate for parallax measurement. These stars were measured respectively by FRIEDRICH WILHELM BESSEL at Königsburg, using a heliometer, by THOMAS HENDERSON at the Cape of Good Hope, using a mural circle, and by Friedrich Georg WILHELM STRUVE at Dorpat, with a filar micrometer on the 24 cm Fraunhofer refractor. Although their figures were revised somewhat by later observers, using larger runs of observations, their parallaxes remain

substantially correct: 61 Cygni, 0".3483; α Centauri, 0".913; Vega, 0".261. In many respects, these parallaxes represented a high-water mark in astrometry, whereby a long-standing astronomical question had been answered by the combined application of higher mathematical theory and superlatively accurate observations made with a new breed of instrument.

The early and middle decades of the 19th century saw the coming of age of manual astrometry (in which the astronomer worked with eyes, hands and ears, without any electromagnetic or photographic aids). This astronomy was directed not only to the definitive establishment of a series of astronomical constants but to the provision of a continuously updated and refined body of data from which original investigations in celestial mechanics could proceed. They came to depend, moreover, on the integrated use of Anglo-German techniques in instrumentation and French mathematical analysis.

The study of binary and triple stars, which had been largely pioneered by William Herschel in 1802, showed a way in which Newtonian gravitation, which hitherto had only been shown to operate in the solar system, was manifestly universal. Bessel, Struve, Sir James South and others across northern Europe had tried to quantify the orbital elements of a binary system, as a way of extracting the gravitational elements of ξ Ursae Majoris and other star systems, and it was Felix Savary, Johann Encke and John Herschel in 1830–1832 who succeeded. Binary star work demanded the highest levels of instrumental accuracy, as equatorially mounted refractors, with achromatic optics by Josef Fraunhofer, Robert Aglaé Cauchoix and others, incorporating micrometer or heliometer functions of the greatest delicacy, made reliable astrometric data available by 1830 that would have been unimaginable in 1780. By 1833, John Herschel was publishing the orbital axial components of six double stars, to four decimal places of a single second of arc, and while many of the hundredths and thousandths of second of arc were subsequently modified, their tenths, as originally measured, rarely needed correction. The refined astrometric investigations of the mid-19th century revealed the presence of many systematic stellar irregularities from which a rich harvest of physical discoveries emerged.

By 1840, all the great observatories of Europe—Königsburg, Dorpat, Berlin, Bonn, Greenwich and others—were primarily concerned with astrometric work, which by that date represented the supreme pinnacle of astronomical achievement. On the one hand, their energies were devoted to the equatorial-refractor-based work of binary star astronomy, although the mural and transit circle also facilitated the routine measurement of meridian positions to within a fraction of a single second of arc. As it was becoming *de rigueur*, in the wake of the examples of Bessel, Struve, Encke, Friedrich Wilhelm Augustus Argelander and George Biddell Airy, for an observatory to publish its work as quickly as possible, a vast body of superlative astrometric data was rapidly becoming available across Europe and America.

It was from this published astrometric archive of meridional data that both John Couch Adams and Jean Joseph Urbain Le Verrier made their spectacular independent discoveries of Neptune in 1846. It was also from relatively long runs of high-quality astrometric data that Bessel was able to quantify a periodic wobble in the position of Sirius from which he was able to compute the presence of Sirius B in 1844. Moreover, both of these discoveries, extracted from existing astrometric data, were followed by telescopic confirmation, when Johann Galle and Heinrich d'Arrest observed Neptune from Berlin on 23 September 1846 and when Alvan Clark saw Sirius B with a new 18 in object glass in Boston in 1862.

The invention of photography in 1839 opened up enormous potential for astrometry. In addition to its capacity for much greater accuracy, it liberated the astronomer from the eyepiece of a telescope, to permit the more comfortable, relaxed measurement of astrometrical positions from photographic plates. However, it was not until after 1881, with the establishment of the *Carte du Ciel*, that photographic astrometry really showed what it could do.

As astrophysics has come to dominate astronomy in the 20th century, however, the fundamental role of astrometry within the science has declined, but the development of radio interferometry in the 1950s introduced a new and important form of astrometry, as radio dishes many miles or even continents apart were used to locate the exact positions of radio sources in the sky to within seconds of arc.

The development of the European Space Agency's HIPPARCOS project in 1989, however, has brought optical astrometry back to a central role once again. The Hipparcos space satellite has enabled the production of excellent astrometric measurements down to 0.002" on a virtually industrial basis without any of the atmospheric problems associated with ground-based observatories. Although astrophysics still contributes much of the driving force of modern astronomical research, critically accurate astrometric data of the kind made possible by Hipparcos are essential, especially as a way of understanding the physical processes going on within our own star system.

Satellite astrometry, indeed, is clearly seen as the way forward when it comes to the most critical accuracies. The forthcoming NASA, FAME (Full Sky Astrometric Mapping Explorer), due to be launched around 2004, will map an incredible 40 million star positions, with an increase in accuracy by a factor of two to ten (depending on magnitude) on previous satellites, during its expected 5 yr of operation. The ESA GAIA (European Space Agency Global Astrometric

Interferometer for Astrophysics), moreover, will also have a 5-yr operational life, in which it is expected that it will map 500 times more objects than Hipparcos, 100 times more accurately.

It could be argued, moreover, that astrometry in its photographic, photo-electric, radio and satellite departments still lies at the heart of astronomical research, for astrophysics itself hinges upon the precise measurement and interpretation of various forms of energy from space. For it is the very act of using instruments to measure and quantify the energy that reaches the Earth from space that makes astronomy by far the oldest of the exact sciences.

Astrometry: Telescopes and Techniques

The goal of astrometry is to determine positions and motions of celestial objects such as stars and planets, as well as artificial satellites. Astrometry is the oldest branch of astronomy and until the 19th century all of professional astronomy was astrometry (see ASTROMETRY: HISTORY). One of the main astrometric objectives is to measure angular separations of stars and other celestial objects relative to reference stars which have known positions. This can be achieved by taking images through a telescope, similar to a camera, be it on photographic emulsion (see DETECTORS: PHOTOGRAPHY) or using electronic detectors such as a CHARGE-COUPLED DEVICE (CCD) as used in most cameras today. Reference star positions are established with methods of absolute astrometry . A catalog of such positions and motions defines a reference system. Most astrometric measurements are made in two dimensions, on the celestial sphere, similar to geographic latitude and longitude. The third dimension, the distance of celestial objects in space, is much harder to measure and one of the biggest astronomical challenges. Only distances within our solar system can be measured with great precision using radar and laser ranging techniques.

Very precise angular measurements on the order of 1 milliarcsecond (mas) can be achieved today by ground-based optical telescopes, astrometric satellites and radio telescopes. An angle of 1 mas is the 1000th part of an arcsecond, which in turn is the 3600th part of a degree. The Moon in the sky measures about half a degree or 1800 arcsec across. A pair of candles 10 cm apart are separated by 1 mas when seen from a distance of 20 000 km.

Not only the Sun, Moon and planets are moving in the sky. If you look closely enough, the 'fixed' stars move as well, slowly circling the center of our Galaxy, the Milky Way. Even galaxies move within clusters of galaxies. Thus precise astrometric positions are time dependent. Without knowing the motions, no good prediction of positions for the future can be made.

A dramatic increase in precision has been achieved in the last two decades, after centuries of slow improvements. In 1980 an absolute position good to 100 mas was state of the art, since 1995 it has been about 1 mas and space missions currently being designed promise 0.05–0.005 mas. This amazing progress is technology driven, taking advantage of new techniques and hardware.

Astrographs and the tangential plane concept

One of the basic astrometric techniques is the use of a camera (astrograph) to map a section of the celestial sphere onto an image surface. A camera here can also be a telephoto lens, a dedicated lens telescope (refractor) or mirror telescope (reflector). The image surface is ideally a plane, orthogonal to the optical axis of the camera, tangential to the sphere. The camera (figure 1) is aimed at the position A in the sky and a star at S is mapped onto S' in the tangential plane. The focal length, f, determines the scale of this mapping:

$$\text{scale (arcsec mm}^{-1}) = 206\,265/[f\ (\text{mm})].$$

The basic idea is to measure rectangular x, y coordinates in the tangential plane, then use the known position of some reference stars in the field to determine the mapping parameters and finally to calculate the spherical coordinates of the other measured field stars. Technical details are explained below.

Wide field

A telescope with a high-quality, wide FIELD OF VIEW of several degrees requires a complex optical design, which cannot be achieved with a two-lens refractor or a two-mirror telescope. Multilens astrographs are the classical telescopes in this category, similar to telephoto lenses. For larger apertures (about 0.7 m or more), catadioptic systems are often used, which are reflecting telescopes with additional lenses. Examples are the SCHMIDT TELESCOPE and large reflectors with 'field correctors'.

These wide-field telescopes are used in astrometry mainly to densify existing reference systems. The positions of many fainter stars are determined with respect to a few bright reference stars with known positions. The large field of view allows for simultaneous observation of a sufficiently large number of reference stars in any given field. The most important examples of astrographs are the Astrographic Catalog (AC) astrographs, built around 1900 with 3.7 m focal length, the Astronomische Gesellschaft Katalog (AGK) series 2 and 3 instruments of 2 m focal length, the five-lens 1975 design of the Hamburg astrograph, the US NAVAL OBSERVATORY (USNO) twin astrograph with its 1990 designed red-lens, and the Lick and Yale 0.5 m aperture astrographs.

The Lick and Yale astrographs use distant galaxies as fixed benchmarks and a set of exposures taken about 20–30 yr apart (epoch difference) to determine absolute PROPER MOTIONS of stars in the Northern and Southern Proper Motion (NPM, SPM) programs respectively. The NPM is complete, while second-epoch observations of SPM in Argentina are in progress.

The USNO CCD Astrograph Catalog (UCAC) project started in 1998 at CERRO TOLOLO INTER-AMERICAN OBSERVATORY and will eventually cover all sky to about 16th magnitude. Positions of stars in the 10–14 mag range are accurate to about 20 mas. Proper motions will be obtained by utilizing new measures of the early-epoch NPM and SPM data.

Narrow field

Long focal length (≈ 10–15 m) refractors and large reflectors provide a field of view of several arcminutes to 1º at high magnification to resolve tiny displacements of stellar images. These telescopes are mainly used in astrometry for the determination of trigonometric PARALLAXES, which is the most direct, fundamental technique to determine distances outside the solar system. Small shifts of position of a relatively nearby target star are measured relative to distant stars, which are selected by spectral and photometric properties. The tangential plane concept is used here as well; however, no precise (absolute) reference star positions are needed. Observations of a given field are obtained over several years and then mapped onto each other, assuming the mean of the background stars fixed.

Figure 2 explains the principle of trigonometric parallax observations. While the Earth circles the Sun the position of a nearby star changes slightly (order 0.5 arcsec or less). The largest shifts are observed from positions 1 and 2, about half a year apart. On the focal plane the positions of a nearby target star and some distant background stars are plotted over the course of a year (neglecting proper motions). A major problem is to estimate the distances (parallaxes) of the background stars. Ideally they should be infinitely far away, thus being at a fixed position, the center of the ellipses shown in figure 2. In that case the observed position change of the target star with respect to the background stars would directly give its true, absolute parallax. In reality, the measurement reveals the relative parallax with respect to the mean parallax of the background stars.

Examples are the refractors of the YERKES OBSERVATORY and ALLEGHENY OBSERVATORY as well as the US Naval Observatory 1.55 m Strand reflector, the most precise and productive instrument in this category. Results of all significant trigonometric parallax and associated proper motion observations are compiled in catalogs issued by the Yale University.

In order to obtain high-precision positions of faint objects such as compact, extragalactic radio reference frame sources, a multistep procedure is adopted. A wide-

field telescope is used to obtain positions of secondary reference stars in the system of primary reference stars. Long-focus instruments continue towards fainter limiting magnitudes and densify the net of reference stars.

Detectors

There are mainly three types of detectors important in optical astrometric programs today: the CCD, the grid modulation photometer and photographic emulsions.

A CCD detector at a telescope is the most important detector, widely used in astronomical data acquisitions. The high quantum efficiency and geometric stability make it a very suitable device for astrometry. The only major problem with a CCD is its relatively small size as compared with a photographic plate. A typical CCD today measures 30–50 mm on a side, while a typical photographic plate can be 100 times larger in area. A mosaic of CCDs can cover a large area in a focal plane; however, gaps remain between chips and, more importantly for precise astrometry, additional parameters in the mapping model are needed for each single CCD chip. This can be a serious problem when the reference star density is low.

The grid modulation technique is applied in the Multichannel Astrometric Photometer (MAP) of the Allegheny Observatory. It measures relative positions of stars in the focal plane with the help of a moving ronchi ruling. This instrument is very precise (3 mas precision per night on a bright target); however, only one target source at a time can be measured with respect to several reference stars. The grid modulation principle is also used in the HIPPARCOS space mission and is explained in figure 3. Photometric measurements with high temporal resolution are made behind a grid in the focal plane. Stars (or the grid) are moving and the phase difference between the signals from two stars gives their precise relative position in fractions of the grid constant. *A priori* knowledge is required for the integer number of grid steps the stars are separated.

Photographic emulsions, on either film or glass plates, require a measuring machine to extract the x, y information of stellar image positions. Photographic emulsions are no longer used in any major current astrometric program. However, the data stored in plate archives are still valuable and their extraction is by no means completed yet.

Measuring machines

In the past humans manually operated one- and two-axis plate measuring machines, centering stellar images on microscope cross-hairs and reading circles. Image dissector techniques can automatically center a stellar image utilizing the symmetry property of the image profile. A complete digitization (scanning) of photographic plates is performed on modern machines. In this case a photometric measurement (transparency or density) is recorded as a function of the x, y position of the scanning detector. This can be achieved by using a microdensitometer, a CCD or a line-scanning device. In all cases an exact measure of the location of the detector with respect to the plate along two axes is critical and most machines use laser metrology or high-precision encoders providing a repeatability of about 0.1 μm. The accuracy is limited by systematic errors in the measuring process and the geometric stability of the photographic media which is on the order of 0.4–1.0 μm, depending on the type of emulsion.

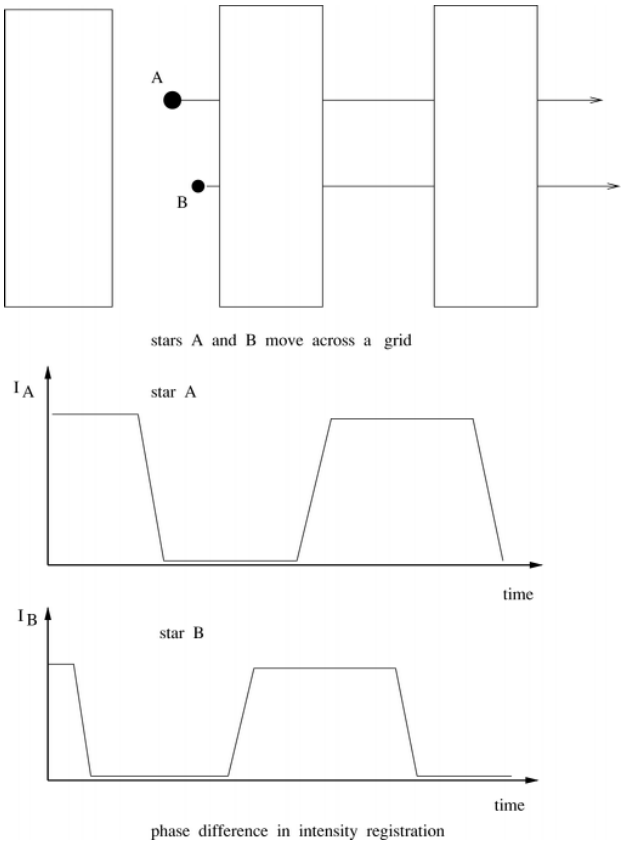

Figure 3. Principle of the grid modulation technique.

Examples are PDS microddensitometer machines, which were commercially available, the GALAXY machine of the former ROYAL OBSERVATORY, GREENWICH the APM at Cambridge, UK, the APS at Minneapolis, the MAMA at OBSERVATOIRE DE PARIS, the PMM of the US Naval Observatory, the HAM1 at Hamburger Sternwarte and the SuperCosmos of the ROYAL OBSERVATORY, EDINBURGH.

Transit circle and absolute astrometry

A transit circle (TC) is a telescope mounted on a fixed east–west axis, so it can move only along the local meridian. The meridian is the great circle through the celestial poles and the zenith, perpendicular to the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

horizon (figure 4). The TC makes two independent observations: the time when a target object crosses the meridian (transit) and an angle, the zenith distance, which is read off circles attached to the east–west axis of the telescope. The zenith direction is determined in practice by looking in the opposite direction (nadir), down into a mercury mirror surface which represents the local horizon plane due to the Earth's gravity. Collimated fiducial marks located some distance towards the north and south are observed to check on the stability of the instrumental azimuth.

In past centuries transit observations were made by the 'eye and ear' method, watching a star crossing the micrometer wire through the eyepiece of the telescope and listening to time signals to estimate the fraction of a second. Modern instruments use photoelectric detectors and follow the star for some time in the focal plane to obtain multiple measures for a single transit.

A TC can perform relative observations; however, it is also capable of absolute (fundamental) astrometry, meaning that it can determine positions of celestial objects without *a priori* knowledge of other star positions. Thus TC telescopes provided the primary reference star catalogs (fundamental catalogs) throughout centuries. The most important are the FK3, FK4 and FK5 series of this century, published by the Astronomisches Recheninstitut in Heidelberg, Germany. Recently, fundamental work with TC telescopes has been superseded by more accurate techniques such as the Hipparcos space mission and radio VLBI observations (see below).

TC observations are affected by a variety of issues. Instrumental imperfections such as flexure of the telescope tube can be determined by appropriate modelling of a series of observations. Critical is the stability of the instrument to repeatably follow the same pattern over a given interval of time. Polar motion, the wandering of the Earth's axis with respect to the surface of the Earth, and other changes of the local coordinate system enter TC observations and need to be resolved. Furthermore, the rotation axis of the Earth is not fixed in inertial space. A coordinate system related to the equator of the Earth is moving with respect to the stars (precession and nutation). The finite speed of light causes astronomical aberration, an angular shift of the observed trajectory with respect to the true position. All those effects enter absolute TC observations to the full extent, while differential (relative) observations have to deal only with variations of those effects over the field of view.

Of particular concern for TC observations is the refraction in the Earth's atmosphere. Observations of both the lower and upper transit of stars near the pole help to determine a refraction model. Nevertheless, refraction is changing with atmospheric conditions such as temperature. The turbulence of the atmosphere ultimately limits absolute TC observations by unmodeled systematic contributions and random noise. Examples of TC instruments are the CARLSBERG MERIDIAN TELESCOPE and the meridian circle at the OBSERVATOIRE DES SCIENCES DE L'UNIVERS DE BORDEAUX and the 6 and 7 in telescopes of the US Naval Observatory.

Scanning TDI technique

A recent innovation in astrometry is the use of CCDs in the focal plane of TC-type telescopes. The CCD can be operated in a time-delayed integration (TDI) mode, where the charge transfer for the CCD readout is synchronized with the motion of the star across the chip. However, this works well only for stars moving along a great circle (equator) and for a small width of a strip being scanned. In all other cases stars in different locations on the CCD move along significantly non-linear paths, resulting in image smearing.

A pioneering instrument of that type is the Flagstaff Astrometric Scanning Transit Telescope (FASTT). The Carlsberg Meridian Telescope (CMC, La Palma and Cambridge, UK) and the Bordeaux TC have utilized the TDI scanning technique for zonal catalogs. The imaging part of the SLOAN DIGITAL SKY SURVEY (SDSS) project also uses the same technique. However, the SDSS telescope can follow arbitrary great circles on the sky by actively steering the telescope and rotating the detector plane at the same time.

Astrolabe

An ASTROLABE is an example of an equal altitude instrument, measuring the time of transit of a star through a small circle of fixed altitude or zenith distance (often 30º or 45º). This is achieved by a mirror–prism configuration in front of a horizontally mounted telescope. Direct and reflected images of a target star are mapped into the focal plane. The apparent motions of both images are in opposite direction, and they cross each other when the star reaches the fixed zenith distance the instrument is designed for. Star positions can be deduced from observations of crossings toward the east and west.

There are two main advantages of an astrolabe over a TC. All stars are observed at a fixed zenith distance, simplifying the corrections for refraction, and the instrumental setup is more stable, avoiding flexure problems. The main disadvantage of an astrolabe is its restricted sky coverage in declination, δ, of $\phi - z < \delta < \phi + z$, with ϕ being the geographical latitude and z the fixed zenith distance of the instrument. As with the TC, the astrolabe's capability to produce a fundamental catalog and monitor the Earth's rotation is now only of historical interest owing to superior accuracies from VLBI and space astrometric techniques.

Photographic zenith telescope (PZT)

A PZT is a vertically mounted telescope with a lens on a rotary stage on top and a mirror at the bottom. With a PZT the relative position of the local zenith with respect to the stars is observed. For decades the PZT was utilized for Earth orientation determination. Since VLBI techniques are now much more accurate, the PZTs are obsolete.

Interferometry

Interferometry is the most accurate astrometric technique currently known, utilizing the wave nature of coherent light (or electromagnetic radiation in general) for angular measurements. Widely used is the Michelson interferometer. Its basic principle is illustrated in figure 5. Two fixed telescopes (sidereostats) A and B observe the same star. The beam from at least one of the telescopes needs to pass through a delay line of variable length, in order to observe the same incoming wave front simultaneously (coherent) and thus obtain an interference pattern (fringes) at the beam combiner. Depending on the position of the star relative to the baseline (angle γ), the delay (d) varies and has to be adjusted accordingly. The basic interferometric measurement is the delay length as a function of time, while keeping the fringe contrast (visibility) at a maximum (see INTERFEROMETRY):

$$\cos\gamma = d/b.$$

With the known baseline b this gives a measure of γ. Observing several stars many times in a night allows us to solve for the positions of the stars and Earth orientation parameters. *A priori* information on the approximate star positions is required to steer the delay line and to obtain fringes. The interferometer then determines d to a fraction of the wavelength, while the baseline length is monitored with additional metrology. An accuracy of a few mas can be obtained with this technique globally and relative measures (double stars, stellar limb darkening) are at least 10 times more accurate. As with transit circles, the properties of the atmosphere are currently limiting the accuracy.

The Mark I (MOUNT WILSON OBSERVATORY) was the first phase-coherent stellar interferometer, followed by Mark II and Mark III (around 1990). Examples of operational optical interferometers are the COAST (Cambridge, UK), SUSI (Australia), GI2T (France), PTI (PALOMAR OBSERVATORY) and the Navy Prototype Optical Interferometer (NPOI). Only COAST and NPOI have three or more sidereostats and regularly can perform imaging. The CHARA instrument has started operation on Mt Wilson. The SPACE INTERFEROMETRY MISSION (SIM) project (approved by NASA for launch in 2009) is based on the same technique.

Similar techniques are used at radio frequencies. The signals I_A and I_B from two radio telescopes are fed into a correlator. The correlator product, C,

$$C = \int_{t_1}^{t_2} I_A(t) I_B(t+\tau)\,dt$$

is at maximum when $\tau = d/c$ with c being the speed of light and d the delay as in figure 5.

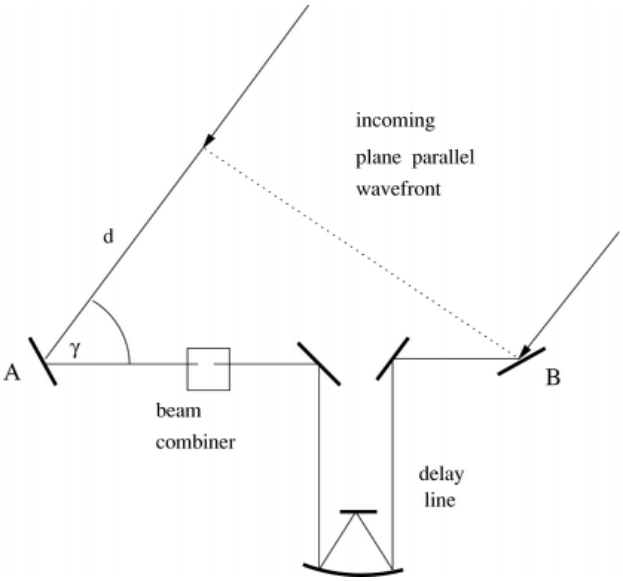

Figure 5. Principle of a Michelson interferometer.

Very long baseline interferometry (VLBI) is the most accurate radio astrometric technique. Here the individual telescopes are usually far apart on different continents and no longer directly connected. Instead, the signal at each station is modulated with a very precise frequency standard (atomic clock, maser), digitized and written to special tapes. The tapes from all stations are later processed at a correlator center and delays and delay rates are extracted as basic information.

The resolving power, R, of an interferometer no longer equals the resolving power of its individual apertures; instead the Rayleigh criterion

$$R\ (\text{rad}) = 1.22\lambda/b$$

holds for the separation of two linked telescopes with a baseline length b. This is particularly important at radio wavelengths, λ, which are very long (millimeter to meter) as compared with optical wavelengths.

Optical interferometers as well as VLBI have the capability for absolute astrometry. VLBI currently has the highest accuracy of all wide-field astrometric techniques. Earth orientation parameters are being routinely obtained on the sub-mas level and the International Celestial Reference System (ICRS) is defined by the positions of 212 extragalactic, compact radio sources observed with VLBI.

Speckle interferometry

Speckle interferometry is a technique to overcome the seeing limitation of ground-based, optical–IR telescopes in very small field applications such as double-star observations. If the aperture of a telescope is large as compared with the Fried parameter ($r_0 \approx 0.15$ m, see ADAPTIVE OPTICS), a large number of individual speckles are seen within the seeing disk when a star is imaged at high magnification. Taking individual images with short integration times (≈1/30 s) allows one to resolve the speckles. The size of the speckles is determined by the aperture of the telescope. The autocorrelation, A,

$$A(u) = \int I(x+u)I(x)\,\mathrm{d}x$$

over the image area reveals the separation and orientation angle (with a 180º ambiguity) of a double star with a resolution similar to the theoretical resolving power of the telescope without the influence of the atmosphere. A more complex structure in the object can be analyzed with Fourier transformation techniques. Speckle interferometry works only within the isoplanatic patch and thus is limited to a field of view of about 5 arcsec.

Space astrometry

The HUBBLE SPACE TELESCOPE (HST) has two instruments for astrometric observations, the Fine Guidance Sensors (FGS) and the Wide Field and Planetary Camera (WFPC). The FGS allow a two-dimensional relative position determination of objects within a ≈13' by 4' annular field of view, observing one target at a time (see ASTROMETRY WITH HUBBLE SPACE TELESCOPE).

The second Wide Field and Planetary Camera (WFPC2) of HST uses four CCD detectors for direct imaging in bandpasses from UV to IR. Astrometric information can be obtained following the tangential plane concept as described in the first section. Optical field angle distortions have been determined with dense calibration fields (globular cluster), reducing the number of parameters required in the mapping model for user applications. The field of view is only about 75" on the three Wide Field CCD chips and about 34" on the Planetary Camera CCD. Correcting optics is integrated in the second WFPC2, which was installed in December 1993. The instrument is suitable for astrometry of very faint sources (to ≈26 mag); however, the images are undersampled and dithering techniques are used for high-precision centering.

Hipparcos, the High Precision Parallax Collecting Satellite, was the first space mission dedicated to astrometry (see HIPPARCOS). Launched in 1989, it observed the entire sky for 3.5 yr, producing a catalog of 118 000 stars with absolute positions, proper motions and trigonometric parallaxes on the 1 mas accuracy level. With a split mirror, two fields in the sky separated by ≈58º were mapped into the same focal plane. The satellite continuously rotated and light from stars crossing the fields was modulated by a well calibrated grid. Using an input catalog, selected spots in the focal plane were picked up by the photoelectric detector. The raw data comprise a steady stream of light intensity measures as a function of time. Only one dimension (along the scan) was observed with high precision. The rotation axis of the satellite slowly precessed to allow for a global coverage of the sky. Each point in the sky was scanned about 120 times with a variety of scan directions in order to resolve both coordinates. Abscissa data, angles measured along the scan direction, of all great circle scans were later combined in a single large reduction (sphere reconstruction) in order to simultaneously determine the astrometric parameters of stars as well as instrumental parameters. As a result, a rigid, self–consistent, instrumental coordinate system was established.

The external orientation of the axes (three position and three proper motion parameters) were provided in combination with ground–based observations, linking the Hipparcos frame to the ICRS. All stars to about 7th magnitude were observed in two bandpasses, similar to B and V, as well as most stars to magnitude 8.5 and some selected to 12.5 mag.

The star mapper data of the Hipparcos mission were utilized to survey all stars to about 11th magnitude in the Tycho project. A re-evaluation of the Tycho data, completed in 1999, produced the Tycho-2 catalog of 2.5 million stars (photometry and position), supplemented by proper motions in connection with ground-based catalogs. The accuracy of the Tycho positions is on the order of 10–70 mas depending on magnitude (see TYCHO STAR CATALOGS).

In 1999, NASA selected the Full-Sky Astrometric Mapping Explorer (FAME) space mission for a scheduled launch in 2004. Similar to Hipparcos, this satellite will scan the entire sky in a 5 yr mission to obtain positions, proper motions and parallaxes of 40 million stars with an accuracy of 0.5 mas–50 μas, depending on magnitude. In contrast to Hipparcos, FAME utilizes an array of CCDs in scanning TDI mode (see above).

A global view of astrometric techniques

More than in many other disciplines of physics and astronomy, a thorough investigation of measuring errors is an essential part of astrometry. The precision of an observation is an internal, formal error, often derived from random error statistics of repeated observations. The accuracy of an observation refers by definition to its true error, which is almost never known precisely. The accuracy is often estimated from external comparisons with results obtained with an independent set of data or technique. The differences between the values of precision and accuracy estimates are caused by systematic errors, and a large fraction of all astrometric effort is to detect and reduce systematic errors.

This starts with the design of astrometric telescopes. One common theme in many astrometric instruments is the built-in feature of reversal. A TC can be lifted out of its mount and put in reversed. An astrograph usually can be shifted from the east side of the pier to the west, in order to take the same field in the sky 'upside down'. A plate measuring machine can measure plates in several orientations. Another feature of astrometric importance is cross-connection and redundancy. Individual TC programs largely overlap in the sky coverage with each other. Hipparcos observed two fields of view widely separated simultaneously, and VLBI uses multiple telescopes and baselines for simultaneous observations of the same source. Combined with appropriate reduction methods this allows one to detect and correct some systematic errors caused by part of the instrumentation.

However, this can only be achieved with stable instruments. Properties of an astrometric instrument must not change with time or they must be monitored and accounted for. Often a non-astrometric telescope such as the Schmidt telescope is used to obtain astrometric results, which then become compromised. Often this is the only available method to obtain some results at all, e.g. positions of very faint stars all over the sky. Because of the revolution in computer technology, it is nowadays cheaper to control and correct instrumental defects afterwards than to start with a rigid nicely behaving instrument in the first place. Examples are the point spread function (PSF) and geometric mapping properties of modern telescope designs, from ground-based wide-field survey telescopes to the Next Generation Space Telescope (NGST) as compared with the PSF of an astrograph.

For an astrometric instrument usually its resolution (Rayleigh criterion) is not the limit of precision. A stellar image profile of about 1 arcsec diameter might very well be centered to 1/100 arcsec precision or better.

Space- versus ground-based techniques

Basically there are three things different in space astrometry as compared with ground based.

1. *Atmosphere*. The lack of the Earth's atmosphere allows for sharper images, not disturbed by a turbulent medium. The higher resolving power directly leads to a better signal-to-noise ratio and to fainter limiting magnitudes. The lack of turbulence also means a significant reduction in random noise for the measurement of angular separations. The atmospheric random error is roughly

$$\sigma_{\mathrm{atm}} \approx k t^{-1/2} F^{1/3} (\cos z)^{-1}$$

with exposure time t in seconds, field of view F in arcminutes, zenith distance z and the parameter k in the range 10–70 mas, depending on atmospheric conditions. The availability of a larger frequency spectrum (including UV and IR) for space-based observations so far has not been of significant importance to astrometry.
2. *Gravity*. Near-zero gravity for space-based instruments directly leads to greater stability and independence of some errors from the pointing direction. However, thermal effects (satellite in sunlight versus shadow) cause other problems and temperature control to 1/100 K levels is often a requirement for astrometric space missions. The gravitational gradient of Earth-based instruments provides a convenient method to define one axis of a coordinate system. This is no longer available with space missions.
3. *Orientation*. Independence of the Earth means no problems with Earth rotation and irregularities of local terrestial coordinate systems. It also means no accessible definition of north or a similar external orientation. The equator has no meaning for space missions and the plane of the ecliptic only weakly enters in light aberration terms.

Tangential plane reduction technique

Refering back to figure 1, let ξ, η be the rectangular Cartesian coordinates defined as zero point at the intersection of the optical axis with the tangential plane (A'), ξ pointing towards east and η north. A gnomonic projection gives the tangential coordinates as

$$\xi = \frac{\cos\delta \sin(\alpha - \alpha_0)}{\sin\delta_0 \sin\delta + \cos\delta_0 \cos\delta \cos(\alpha - \alpha_0)}$$

$$\eta = \frac{\cos\delta_0 \sin\delta - \sin\delta_0 \cos\delta \cos(\alpha - \alpha_0)}{\sin\delta_0 \sin\delta + \cos\delta_0 \cos\delta \cos(\alpha - \alpha_0)}$$

with α, δ being the right ascension and the declination of S and α_0, δ_0 those of A. The unit for ξ, η is radians at this point.

Measured coordinates *x*, *y* if exactly parallel to ξ, η are then

$$x = f\xi \qquad y = f\eta$$

with *f* being the focal length and *x*, *y* in the same units as *f*, e.g. millimeters. Equation (8) actually is the simplest physical model between the purely mathematical ξ, η and the real-world observables *x*, *y*. An example of a more realistic plate model is

$$\xi = P_1 x + P_2 y + P_3 + P_5 x + P_6 y + P_7 x^2 + P_8 xy + P_9 xr^2$$

$$\eta = -P_2 x + P_1 y + P_4 + P_6 x - P_5 y + P_7 xy + P_8 y^2 + P_9 yr^2$$

with P_1 to P_9 being parameters to be estimated in an adjustment process using reference stars with known positions (ξ, η), and $r^2 = x^2 + y^2$. Parameters 1 to 4 represent an orthogonal model, which is usually the simplest practical model. It allows for a zero point, scale and rotation (alignment) between the *x*, *y* and ξ, η. Including the P_5 and P_6 terms gives a full linear model. Parameters 7 and 8 represent a tilt of the focal plane with respect to the ideal tangential plane, and P_9 is the third-order optical distortion term, significant in most real telescopes. Once the parameters are estimated, a model function such as equation (9) gives ξ, η coordinates from measured *x*, *y* of any star with previously unknown position. Its spherical coordinates, α, δ are then obtained by solving

$$\cot\delta \sin(\alpha - \alpha_0) = \frac{\xi}{\sin\delta_0 + \eta \cos\delta_0}$$

$$\cot\delta \cos(\alpha - \alpha_0) = \frac{\cos\delta_0 - \eta \sin\delta_0}{\sin\delta_0 + \eta \cos\delta_0}$$

Advanced topics and reduction methods

Systematic errors in positions depending on magnitude (called the magnitude equation) are a common problem in many traditional astrometric techniques, particularly in photographic astrometry. Except for external comparisons these systematic errors can be determined by observing images of the same star with different exposure levels. Obviously this can be achieved by taking the same fields with different exposure times. Another option is to use a DIFFRACTION GRATING in front of the aperture (near the entrance pupil). Besides the zero-order central image, the grating produces much fainter, higher order images spaced symmetrically around the central image. Those images are spectra in principle; however, depending on the grating constant and bandpass they can be made almost circular. Instrumental magnitude equations can also be reduced by combining data taken with the instrument in normal and reversed positions. However, guiding error induced magnitude equations cannot be reduced with this technique. With linear detectors such as CCDs, magnitude equations in principle are no longer expected. Nevertheless, with non-perfect charge transfer efficiencies a coma-like systematic error can be significant in CCD data.

Block adjustment (BA) techniques in astrograph-type observing can achieve wide-angle (up to global) astrometric results using only differential narrow-field observations. Overlapping fields are required. Instead of solving for each individual field separately, a reduction scheme is used to solve for all plate parameters and all star positions simultaneously utilizing the fact that a given star has a unique position on all photographs or CCD frames it is on.

This technique was introduced in astronomy in 1960; however, it was not exploited until the 1970s because of a lack of computer power. The method is very sensitive to any systematic errors not modeled in the data and if not applied properly can produce worse results than a traditional reduction.

The sphere reconstruction process of the Hipparcos project actually is very similar to the BA. Because of the larger number of observations per star and the simultaneous observation of two widely separated fields the Hipparcos data are better conditioned for a global solution than overlapping plates.

State of the art accuracies and limitations

Currently the most accurate positions are obtained from VLBI radio observations for a couple of hundred compact, extragalactic sources. Positions for some sources are believed to be accurate to 0.1 mas. Source structure is a serious problem as well as atmospheric and ionospheric properties and the stability of ground-based stations (modeling of short-period effects). VLBI is also a very expensive technique to maintain and mainly is supported for Earth orientation work and geodesy, good astrometry being obtained as an aside.

Interferometric techniques in principle have a better potential for the highest positional accuracy than other methods. However, observing is slow, one object at a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

time. The highest angular resolutions and most accurate astrometry of close double stars are obtained by optical interferometers (NPOI, 70 μas).

Parallaxes on the 0.5 mas level are achieved for well-observed stars by traditional ground-based long-focus telescopes equipped with CCDs, perfoming as well as the best space-based instruments, with the FGS of HST (0.4 mas). However, the ground-based technique is at its theoretical limit set by the atmosphere and next-generation space missions are likely to improve on this by a factor of 10.

The Hipparcos catalog is currently the most accurate realization of an optical reference frame, giving positions of 118 000 stars on the 1 mas level. With a proper motion error of about 1 mas yr^{-1} and a mean epoch of 1991.25 the position errors for epoch 2000 already are of the order of 10 mas. The most accurate positions for the majority of the 9–12 mag stars are currently provided by the Tycho-2 catalog (20–70 mas). Ground-based wide-field astrographs are already capable of improving on this, getting 20 mas down to 14th magnitude (UCAC project). The limit here again is the atmosphere in combination with the available integration time owing to scheduled project duration and the limited field of view. A successful FAME space mission is likely to make future astrograph-type astrometric surveys obsolete, down to its limiting magnitude of 15. Going to fainter magnitudes will remain the domain of ground-based astrometric telescopes for at least a decade owing to their cost efficiency. The USNO A2.0 and the GSC-2 (Space Telescope Science Institute) are currently providing the only all-sky positions (approximately 0.2 arcsec) of faint stars down to 20th magnitude. These are derived from Schmidt survey plates, measured with the PMM. For even fainter stars only small selected areas have so far been observed.

Space-based interferometers such as SIM will push the astrometrical accuracy into the few microarcsecond range; however, only for few selected sources. Ultimately the achievable positional accuracy will depend on the signal-to-noise ratio, and thus the number of collected photons, and the success in controlling systematic errors, which will remain the most important technical challenge for astrometric projects.

Obtaining high-precision proper motions is problematic right now and utilizing decade- or century-old photographic data to their full capacity is an active task in current astrometry. This is likely to change in the future, when all magnitudes of old-epoch data will be covered by a successful next-generation astrometric space mission.

Astronomical Institute of Athens

The Astronomical Institute of Athens is the oldest research institute of modern Greece (it faces the Parthenon). The Astronomical Institute (AI) of the National Observatory of Athens (NOA) started its observational projects in 1847. The modern computer and research center are housed at the Penteli Astronomical Station with major projects and international collaborations focused on extragalactic astronomy.

Currently the 1.2 m telescope at Kryoneri (Peloponnese) is the observational facility of the AI. The AI's most prominent recent project is Aristarchos, the new 2.3 m Ritchey–Chrétien telescope build by Zeiss to be installed at Roania (2340 m altitude).

Astronomical Observing Notebooks for Amateurs

An observational astronomer must, above all, be systematic. A faulty observation is worse than useless, it may easily confuse any subsequent analyses. Keeping careful, accurate records is essential. A story may here be relevant, although it may be apocryphal; it has been quoted time and time again. In 1781 William Herschel discovered the planet Uranus, and looking back on old records it was found that Uranus had been seen on several occasions, although it had always been mistaken as a star. According to the story, the French astronomer Le Monnier (see LE MONNIER) saw it no less than six times, and had he compared his observations he could hardly have failed to make the discovery even though Uranus was at that time near one of its stationary points. Le Monnier failed to check, and one of his observations was subsequently found scrawled on the back of a paper bag which had once contained hair perfume.

In any observation—visual, photographic or electronic—a few necessary notes must be attached. If any of these is omitted, the observation promptly loses much or the whole of its value. Basically, the main requirements are

name of observer
date
time, GMT (never use variants such as summer time in Britain, or time zones in other countries)
equipment used (for a telescope, type, aperture, magnification; for a camera, type, film, exposure time)
seeing conditions
plus any other data which seem to be relevant.

Of course, the type of notebook used depends entirely on the nature of the observations which are being made. The 'old-fashioned' planetary observer would keep a separate book for each object—one for Jupiter, one for Mars and so on. When making a sketch of a planet, or a lunar feature, much depends on the artistic skill of the observer. Some are able to make 'finished' drawings when actually at the telescope; others make preliminary sketches, go to a desk in order to make final copies and then re-check at the telescope. There can sometimes be a temptation to postpone making the final copies until the next day. This must always be resisted; errors are virtually certain to creep in.

Planetary observers often use a scale of seeing devised by E M ANTONIADI long ago. There are five grades, from 1 (perfect conditions of clarity and steadiness) down to 5 (conditions so poor that there would be no point in observing at all except to follow some phenomenon which will not recur). In practice, Antoniadi 1 is very seldom found, at least from countries such as Britain. When making a drawing of Jupiter or Mars, it is helpful to use a prepared disk to allow for the flattening in the case of Jupiter, or the phase in the case of Mars; this is not so easy with Saturn, where freehand sketching is really the only answer.

Photographs should be very carefully filed, with dates and times added as well as other necessary data. The same applies to electronic records. Many amateurs now hunt systematically for novae, comets, supernovae in external galaxies (see AMATEUR–PROFESSIONAL COLLABORATION IN ASTRONOMY), and with these records it is the time which is all-important, particularly if a discovery is made and the observer is anxious to claim priority.

All in all, the method of keeping an astronomical notebook is a matter of common sense. Never record anything of which you are not absolutely certain; if there is a trace of doubt, note it by the side of the observation. Remember, too, that it is only too easy to 'see' what one half expects to see. This was shown very clearly with observations of Mars before and after the first images were sent back by the space probes. Until then, many perfectly honest observers had shown an intricate network of canals. As soon as it became clear that the canals did not exist, they vanished from the observers' notebooks.

One extra point is worth making here. No observation is of much real use if it is left lying fallow in a notebook; if needed for analysis, it must be sent away to an organization such as the BRITISH ASTRONOMICAL ASSOCIATION or the AMERICAN ASSOCIATION OF VARIABLE STAR OBSERVERS. However, to send away one's original notebook is the height of folly; it will probably be mislaid somewhere or other, and perhaps lost in the post. Before sending away an observation, either a drawing or a written record, make absolutely certain that you have a perfect copy. True, this takes time, but it is well worth while.

Astronomical Photography by Amateurs with Telescopes

The modern amateur astronomer is capable of taking beautiful pictures of the night sky, often with surprisingly humble equipment. One of the best ways to get started is to place a single-lens reflex (SLR) camera on a sturdy tripod, open the lens aperture as wide as possible and take a 10 min exposure (see WIDE-FIELD ASTROPHOTOGRAPHY). This will record the stars as trails, because of the rotation of the Earth, and is a good way to show the different colors of the stars. Shorter exposures (typically 1–2 min) will record the stars as points and are a good way of showing the different constellations. Transient events such as aurorae and bright comets can also be photographed in this way.

Unfortunately, modern SLR cameras are not really suitable for astrophotography as they rely on batteries to keep the shutter open. Astrophotographic exposures can be quite long (up to 1 h) and these will drain the camera's batteries very quickly. The best type of camera for this work is those which were manufactured in the late 1970s, such as Nikon, Pentax and Canon. These are rugged, manual cameras and can be purchased for reasonable prices from most second-hand camera shops.

The choice of lenses is also important. Wide-angle to standard lenses are excellent for producing constellation and Milky Way pictures. Small telephoto lenses (135 mm) are good for pictures of larger star clusters and deep sky objects as are long focal length telephotos (200–500 mm), but the latter can be used for eclipses and comets.

For long exposures it is necessary to place the camera on a driven equatorial mount. In this way the camera can track the motion of the sky and produce pinpoint images of the stars. Once the mount is accurately polar aligned it is possible to take exposures up to 30 min without having to make any drive corrections. A useful piece of equipment for this type of astrophotography is a 'ball-and-socket' joint that fits between the camera and mount and allows the camera to point in virtually any direction. Another piece of very useful equipment is a locking cable release to hold the shutter open for extended periods. Closing down the lens aperture by one f/stop (i.e. $f/2$ to $f/2.8$) dramatically improves the quality of star images, particularly around the edges of the frame.

Attaching the camera to a modern telescope allows detailed photography but means that the drive system has to be more accurate. The camera is usually attached by placing an adapter between the rear cell of the telescope focuser and the camera body. Good photographic targets include the Moon (see MOON, MOON MAPS) and this is probably the easiest form of telescopic photography as, because of the Moon's brightness, exposure times can be quite short. Capturing a sequence of the Moon's changing phases can be rewarding as can the eerie spectacle of a total lunar eclipse.

For all types of astronomical photography it is a good idea to bracket the exposures. This means that a series of varying exposure times around the likely correct exposure time are used. By doing this, a correct exposure will usually be attained, and, by noting the exposure time that gives the best result, a more educated guess can be made the next time a similar object is photographed under similar conditions.

The Sun (see SOHO (SOLAR AND HELIOSPHERIC OBSERVATORY) is also a good photographic target but great care must be taken when observing the Sun as even glancing at the Sun in the sky can damage the eyes. Care must also be taken with equipment as the heat from the Sun can damage lenses if they are pointed directly at the Sun for too long. The easiest and safest method of solar photography is to project an image of the Sun onto a piece of white card and photograph the image directly on the card. In this way it is possible to photograph sunspots on a daily basis. Full-aperture and off-axis solar filters give good views of sunspots. Advanced amateurs also use hydrogen alpha filters to photograph the Sun at a very specific wavelength, chosen to show the dramatic prominences that are visible around the edge of the Sun. Although expensive, these filters produce stunning results, especially when the Sun is in an active phase. The large amount of light given off by the Sun means that photographic exposures can be kept short.

To photograph the planets, which have very small angular diameters, an option is to use eyepiece projection. This involves placing an eyepiece between the telescope and camera to project a highly magnified image of the planet onto the film. Although capable of producing good results it is usually quite difficult because of the unsteadiness of the Earth' s atmosphere (poor seeing) and the difficulty of focusing on such a faint image.

Deep sky photography of galaxies and nebulae (see figures 1 and 2) is rewarding but requires very good tracking from a polar-aligned equatorial drive. Although most modern telescopes are equipped with accurate drives during longer exposures it is necessary to make minor corrections to the tracking of the telescope. Traditionally, this has been done in one of two ways. A separate telescope can be attached to the mount and used as a guidescope to monitor any deviations from perfect tracking performance. This method works well as bright stars which are suitable for guiding are usually easy to find. The guidescope needs to be fixed rigidly otherwise flexure can occur which will degrade the guiding. The second method involves the use of an off-axis guider, attached between the telescope and camera, which diverts the light from a guidestar using a small prism or mirror. These work well as the guiding is carried out through the main optics of the telescope, so no flexure

Figure 1. The Pleiades, a young star cluster surrounded by a reflection nebula, photographed by Nik Szymanek.

Figure 2. The Lagoon Nebula, M8, a diffuse emission nebula in Sagittarius, photographed by Nik Szymanek.

occurs, but can be difficult in practice as the choice of suitable guidestars is severely limited. A modern option is to use a charge-coupled device autoguider (see CCDS, FILTERS AND CCD PHOTOMETRY FOR AMATEURS) with the guidescope as this will deliver the best tracking of all and alleviates the need for an observer to peer through a guiding telescope during long exposures.

Focusing on deep sky objects is quite demanding and is best achieved by using a moderately bright star and racking the focus back and forth until good focus is attained. If the camera used has the facility to change the focusing screen, a good option is to install a high-transmission screen such as those manufactured by Beattie. These feature very bright views and minimal clutter as no 'daytime' focusing aids (split image) are necessary.

Traditionally, fast films have been used for deep sky astrophotography (generally 400–1600 ISO), but one of the best films to emerge for this kind of photography is Kodak EliteChrome 200 ISO slide film. Several characteristics, such as fine grain and good red sensitivity, make it an excellent performer. Also, the digital manipulation of astrophotographs is very popular among modern astrophotographers. Film can be scanned and digitally enhanced to remove light pollution, aircraft and satellite trails, as well as contrast and color enhanced in what is effectively a digital darkroom.

Astronomical Societies and Publications

The first publicly sponsored, modern observatories came into being to serve the needs of navigation and time-keeping, and their first publications were, correspondingly, in the form of almanacs, ephemerides and the like. Early arrivals on the scene included *La Connoissance des Temps* (Paris Observatory, 1679) and *Nautical Almanacs* (Greenwich Observatory, 1767; San Fernando Observatory (Spain), 1792; US Naval Observatory, 1855). Producing calendric and navigational data appropriate to specific locations and languages was also a major function of the far more numerous observatories of the 19th century.

Professional societies (and publications) serve to validate a scientific community and its shared store of knowledge, customs and experiences. The first scientific society, however—the Royal Society of London, founded in 1660—was largely amateur. Its *Philosophical Transactions*, begun in 1665, for the first time facilitated the rapid dissemination of new scientific discoveries as well as providing a forum for their critique.

The first specifically astronomical society was the Astronomical Society of London (soon to become the ROYAL ASTRONOMICAL SOCIETY (RAS)), founded in 1820 by John Herschel and others (see HERSCHEL FAMILY) to supply a need that was not being satisfied by the Royal Society. Jewish names appear in the early membership lists, long before Jews were admitted to English universities, and a woman, Caroline Herschel, received a medal in 1828; the second was Vera Rubin, in 1996. Publication of the Society's *Memoirs* began in 1821, and they at first consisted of papers that had been presented in brief form at the monthly meetings. Soon it was necessary for the editors to point out that thanking a speaker for his presentation did not necessarily reflect unqualified approval or guarantee space in the *Memoirs*. A small committee reviewed contributions from time to time and recommended to the Council of the Society which ones should be published. Thus the *Memoirs* can claim to be both the first specifically astronomical publication and the first such publication to be refereed.

Memoirs, however, made no provision for less substantial items such as advance notices of meetings, short notes on astronomical phenomena and reports from observatories, and so in 1827 the Society instituted its *Monthly Notices*. This developed and eventually increased its frequency; it now appears thrice monthly and is a leading journal in the field. *Memoirs* became a vehicle for the publication of very long papers and compilations of data, and in 1977 it self-destructed in favor of microfiches in *Monthly Notices*. Early issues of both journals had occasional items in French but were monoglot for most of their histories.

The other astronomical publication to appear in the 1820s, *Astronomische Nachrichten*, was the fruit of the enthusiasm of a single man, Heinrich Christian Schumacher, director of the observatory at Altona from 1823 until his death in 1850. *Astronomische Nachrichten* continued to be edited at Altona, first by C A Peterson and then, from 1855, by C A F Peters. In 1872 the Altona observatory was moved to Kiel, and the journal was edited from there until the 1930s, when it was moved to Berlin. Schumacher offered to publish articles in 'any European language'; contributions in French and English were common from the start, and today nearly all the articles are in English.

Another publication that was the creation of a single person appeared in the USA: *Astronomical Journal*, founded by BENJAMIN APTHORP GOULD in 1849 in deliberate imitation of the German periodical. Its pages were open to professionals and amateurs alike, worldwide. Publication was interrupted by the Civil War, but Gould resumed it in 1886. *Astronomical Journal* is now published by the AMERICAN ASTRONOMICAL SOCIETY.

An oddity among astronomical publications is *The Observatory*, founded in 1877 and to this day owned collectively by its current editors. In addition to short research papers, it carries meeting reports, reviews and light-hearted items.

France produced a wide range of journals, beginning in 1884 with *Bulletin Astronomique*, published at the Paris Observatory but not limited to work done there. The Société Astronomique de France, and its *Bulletin*, were founded in 1887 (see SOCIÉTÉ FRANÇAISE D'ASTRONOMIE ET D'ASTROPHYSIQUE), and the *Journal des Observateurs* was founded in 1915. In 1969 this and the *Bulletin Astronomique* were merged into *Astronomy and Astrophysics*, together with *Annales d'Astrophysique*, *Zeitschrift für Astrophysik*, and the *Bulletin of the Astronomical Institute of the Netherlands*, which had been founded in 1921 by five Dutch observatories and institutes that had previously produced their own publication s

In 1863, German astronomers founded a society, ASTRONOMISCHE GESELLSCHAFT, in the context of the gradual unification of the country; it began its own publications soon after, and late in the century assumed responsibility for *Astronomische Nachrichten*. Other national societies founded in the 19th century were Società Astronomica Italiana (whose *Memorie* appeared from 1872), Société Royale Belge d'Astronomie (*Ciel et Terre* from 1880, *Bulletin* from 1895), the Royal Astronomical Society of Canada (founded in 1868) and the American Astronomical Society (1899).

Periodical literature in the late 19th and 20th centuries

The rise of 'astrophysics' in the later decades of the 19th century led to the involvement in the 'new' astronomy of scientists from a wide range of disciplines, and this sometimes led to strain between them and the 'old' (positional) astronomers. In Britain the RAS and its publications managed to absorb the new topics. The

American community partially fractured with the founding of the *Astrophysical Journal* (*ApJ*) in 1895 by George Ellery Hale and his associates. At first it mostly published spectroscopic results from Yerkes and, soon after, Mount Wilson Observatories, with some resistance from astronomers at other locations. It eventually spread over the entire country (and later the world) and embraced all aspects of astronomy, although there have been times when the editors thought it necessary to say explicitly that they would welcome papers in radio astronomy and astronomical instrumentation, invitations that not all found convincing. *ApJ*, originally owned by Yerkes Observatory, is now published by University of Chicago Press, but with management provided by the American Astronomical Society. It has been absolutely monoglot from the beginning.

The German and French communities also fragmented as they grew, with the founding of *Zeitschrift für Astrophysik* in 1930 and *Annales d'Astrophysique* in 1938, both originally monoglot but with numerous papers in English by the time they were absorbed into *Astronomy and Astrophysics* in 1969. No other national communities seem to have been large enough to support two professional publications, and astrophysicists elsewhere turned to academy proceedings and journals of physics in their home countries or, increasingly, to the *ApJ*.

Further fragmentation of the astronomical literature is a relatively late development, except for specialized publication in meteoritics (from 1935 onward in the USA and 1941 in the USSR) and selenography, both tied to specialized societies. Publications focusing on the Sun and solar system, and parallel divisions of the American Astronomical Society and some other professional societies, appeared after the Second World War.

In the second half of the 20th century there have been two main drivers of the establishment of new societies and publications. In the more advanced of the developing countries, and in those resulting from the dissolution of the USSR, Yugoslavia and Czechoslovakia, astronomers have often started their own, typically quite small, societies. Countries with still smaller populations of professional astronomers usually adhere to the INTERNATIONAL ASTRONOMICAL UNION via a national committee under the auspices of the national academy of sciences.

New journals have come largely from commercial publishers, sometimes with encouragement from members of the astronomical community who felt inadequately served by the older publications. None of these is currently a serious competitor, in the sense of being both large and highly regarded. In fact, as we shall see, the dominant trend has been towards a further concentration of important papers into the largest refereed journals, all of which are now published almost exclusively in English. The extent to which electronic publishing will modify current patterns remains to be seen.

Already in the 19th century, some astronomers perceived that the literature was becoming too voluminous for everyone to scan it all. An attempt at a *Bibliographica Astronomica* lasted only a year or two (around 1895). More successful was the *Astronomischer Jahresbericht*, begun by the Astronomische Gesellschaft in 1899, with the abstracts initially all in German (but article titles normally in the original language). It survived both world wars (although with incomplete coverage of the literature during the second) and in 1969 was transferred to a commercial publisher and English language text, as *Astronomy and Astrophysics Abstracts*.

Amateurs in astronomy

From its foundation, the Royal Astronomical Society welcomed both full-time and part-time, paid and volunteer, professional and amateur astronomers. However, as its activities and publications focused increasingly on the interests and products of the full-time, paid, professional sector, amateur astronomical societies inevitably came into being. Of those that survive, Leeds (1859) was the first and Liverpool (1881) the second, followed by the broader-based British Astronomical Association in 1890. The Association's *Journal* began publication the same year and still flourishes.

In the USA, amateur societies came first, Chicago (1863) and Baltimore (1881) pre-dating the founding in 1899 of the American Astronomical Society. The Astronomical Society of the Pacific and its *Publications* date from 1889. A 'pro/am' organization from its foundation (in connection with the coordination of observations of a solar eclipse visible from California), it has remained so, although eventually separate publication series became necessary, the *Publications* serving the paid professional and a series of *Leaflets* (1925–71) and, more recently, the journal *Mercury* being targeted at amateurs.

The AMERICAN ASSOCIATION OF VARIABLE STAR OBSERVERS, founded in 1911, is an amateur-dominated joint organization whose contributions to astronomical research are approached only by the somewhat similar Association Française des Observateurs d'Étoiles Variables (1921) and, in its day, by the Observing Corporation of the Society of Amateur Astronomers of Moscow, whose *Bulletin* (1925–1937) was later incorporated as one of the publications of the Academy of Sciences of the USSR.

International collaboration

International collaboration in astronomy began in the 18th century with cooperation over expeditions to observe transits of Venus, and in 1800 at Lilienthal there was organized a corps of 24 'celestial police' to monitor the ecliptic in search of a planet between Mars and

Jupiter as predicted by Bode's law. The projects that resulted in the massive *Bonner Durchmusterung* (of stars), begun in 1859, and its southern extension, the *Cordoba Durchmusterung*, were largely parochial, but led to an agreement among 17 observatories to provide very accurate positions for the *Durchmusterung* stars down to ninth magnitude. However, work proceeded slowly and was overtaken by the advent of dry-emulsion photographic plates.

Successful photography of astronomical objects at many observatories led the director at Paris, Admiral E B Mouchez, with support from David Gill at the Cape of Good Hope, to attempt from 1885 the coordination of an international *Carte du Ciel*, a photographically based map of the sky and accompanying catalog of positions and magnitudes down to 11^m. The Permanent International Committee and its *Bulletin* (1892–1915) lasted until the onset of the First World War, holding regular conferences, encouraging progress among the 20 or so observatories and arranging for publication of portions of the *Carte* as material became available. The work was actually completed only in 1964, but the earlier plates are a valuable resource for determining proper motions over a long period.

Initially successful, but also a victim of the First World War, was the International Union for Co-operation in Solar Research (*Transactions* published from 1906 to 1914), whose prime mover was Hale. The Union attempted, for example, the standardization of measurements of solar rotation, so that real variations with latitude and with time could be identified. Last on the pre-war scene was Jacobus Kapteyn's scheme for Selected Areas (so that measurements of stellar brightness, color, proper motion, radial velocity and so forth could be concentrated in parts of the sky that would best reveal the large-scale structure of the Galaxy).

In 1919 representatives of 16 of the victorious nations met in Brussels to form the International Research Council (now International Council of Scientific Unions or ICSU), for which the cooperation of neutral nations was invited. The organizational meeting for the International Astronomical Union took place at the same time. An additional 16 nations were declared eligible for IRC membership over the next few years, an important constraint on the IAU, since no country could join it (or, initially, even send people to its meetings) without acquiring IRC membership first. The first official General Assembly of the IAU was held in Rome in 1922 and nine countries (Belgium, Canada, France, Great Britain, Greece, Italy, Japan, Mexico and the United States) participated. By the second Assembly the number had grown to 22. China and the Soviet Union were important additions between the world wars, but Germany, Austria, Hungary, Bulgaria and Turkey were still unwelcome until after 1945. The IAU eventually assumed responsibility for both the *Carte du Ciel* and the Selected Areas, although with some difficulty, since both had considerable German involvement. After the Second World War it took charge of the collection and dissemination (via telegram and, more recently, e-mail) of rapidly breaking astronomical news.

The IAU membership of some 150 astronomers at its foundation has now grown to about 8000 in 81 countries. From its beginning the IAU had its own series of publications, at first simply the reports of the triennial General Assemblies, but now including the proceedings of the specialized symposia and colloquia sponsored or endorsed by the IAU. The Union has become increasingly active in promoting astronomical education and research in developing countries, and it remains unique among the international scientific unions in having individual members as well as adhering countries.

Patterns of publication

A leading 19th century astronomer might well publish half or more of his papers in non-astronomical journals, and nearly all produced books recording their more extended efforts. A century later the astronomer or astrophysicist is likely to publish all his or her non-conference papers in one or another of the very few specialized, prestigious journals, and to produce monographs only of the textbook or trade book variety, if at all.

Changes over the first half of the 20th century are revealed by an analysis of the volumes of the *Astronomischer Jahresbericht* for 1900, 1925 and 1955 (these last dates being chosen to avoid distortion by the world wars). The first and most obvious trend is the growth of the field: not only do the numbers of papers increase, but their mean length has grown enormously. The second is the gradual shift between observation and theory, a shift that has doubtless continued in recent decades, although many of today's 'observations' (like the abundance of an element in a star derived from its spectrum) would have counted as theory in 1925 (and witchcraft in 1900). Third, the heyday of observatory publications came between the wars, when more than 200 existed, and they contained about one-sixth of the papers, compared with one-tenth in 1900 and in 1955; that fraction has now fallen much lower. The fourth trend is in the changes in the balance between nations, most notably in the increase in the contributions from the United States. Finally, and still more obviously if one looks at more recent times, is the gradual concentration of 'publishing power' in a few editorial hands. In 1997, 5272 pages appeared in the *Astronomical Journal*, 9136 in *Monthly Notices*, 17 141 in *Astronomy and Astrophysics* and its *Supplement* series and 22 948 in *Astrophysical Journal*, its *Letters* and *Supplements*. Nothing else (except perhaps conference proceedings and abstracts) remotely competes in size and level of quality as perceived by the astronomical community.

Astronomical Society of Australia

The Astronomical Society of Australia (ASA) was formed in 1966. It has a membership of professional astronomers and has as its objectives 'the promotion and extension of knowledge of Astronomy and related branches of science'. The business of the ASA is conducted by an elected Council. It is represented on a number of astronomical bodies such as the National Committee for Astronomy. The Society publishes an international journal, *Publications of the Astronomical Society of Australia*, and it holds an annual four day scientific meeting.

Astronomical Society of the Pacific

The Astronomical Society of the Pacific (ASP) has worked since 1890 to advance astronomy, and to explain the universe to students, teachers and the public. It is the world's largest general astronomy organization. Its annual meetings bring together professional and amateur astronomers, historians, teachers, students and the public. It publishes a respected professional journal *Publications of the ASP*, the ASP Conference Series containing the proceedings of over 200 astronomy conferences, and the non-technical magazine *Mercury*. It is also the publisher for the INTERNATIONAL ASTRONOMICAL UNION. Its quarterly teachers' newsletter *The Universe in the Classroom* reaches thousands of classrooms, and is translated into a dozen languages. It also produces a wide range of high-quality, low-cost teaching resources, including books and slides. It co-manages the education and public outreach program for NASA's SOFIA airborne observatory. Its exemplary Project ASTRO develops productive long-term partnerships between astronomers and teachers across North America.

Astronomical Spectroscopy

As a passive science, astronomy extracts most of its information from the incoming RADIATION out of the heavens. Such an analysis would be all too simple were it not for the quantum nature of matter and radiation. Electrons are bound in quantized orbits around their nuclei and must emit radiation at discrete wavelengths which are defined precisely by the transitions between discrete energy states. The resulting spectral lines are extremely important tools for identifying and characterizing the emitting source.

Spectral signatures

The first concept of spectroscopy can be traced to Newton, who first noted that the dispersion of sunlight into its different colors by a prism reflected the properties of sunlight itself. It is furthermore remarkable that some 200 yr later, in the late 1800s, when Balmer recognized the hydrogen series in the absorption lines of the solar spectrum first seen by Fraunhofer, it pre-dated the discovery of the electron, the quantum theory or the Bohr atom. This hint from the heavens, that matter will absorb light in a very well-behaved manner, with a SPECTRUM which can be modeled as the hydrogen series and which can be applied to other atomic species, motivated the development of modern physics. Today, we know of course that the quantized energy states of an electron orbiting an atom depend on the mass of the nucleus and the nuclear charge. Each isotope of each atomic species therefore has a distinctive set of electronic levels. Hence the resulting transitions form a unique and unambiguous signature for identification.

Measuring large-scale motions

Perhaps the most important feature of the atomic spectra is the rest frequency or wavelength of the transitions. These are very precisely known, either through quantum mechanical calculations or laboratory measurements, to typical accuracies of better than one part in a billion. This high accuracy allows the measurement of any shift in the rest wavelength due to the motion of the emitting source. The Doppler shifts, measured through precise spectroscopy, have been the cornerstone of modern astronomy. Such diverse phenomena as binary stellar orbital motions, rotation curves of galaxies and radial motions around massive black holes represent a few examples of the important kinematic motions revealed through spectroscopy. Perhaps the most important measurement of all was the recognition of the Hubble flow of galaxies. The systematic REDSHIFT of the spectra of galaxies, the recognition of their cosmological nature and the ever-increasing magnitude of motions with distance are the foundation of the model of the expanding universe. This result has the enormous implication that the light which we observe at different redshifts comes from different distances. Because of the finite speed of light, this means that we have the means to examine the history of the universe as a function of time, by sampling only in our own epoch. In the past decade, the redshifted Doppler motions of galaxies have been used to map the spatial distribution of matter on very large scales, suggesting the formation of structures in the very early universe. The study of galaxies and QUASARS at very high redshifts has become one of the fundamental problems of modern astrophysics.

Measuring local motions

Because of the discrete nature of the electronic energy states, the ensuing transitions not only have precisely determined transition frequency but also intrinsically narrow line widths, typically dominated by Doppler motions within the emitting systems. When spectrometers became powerful enough and the detectors became sensitive enough, line profiles began to be resolved. The measured spectral profiles were found to carry important information on the local kinematics. For example, extraordinarily broad line profiles seen toward SEYFERT GALAXIES were interpreted as outflowing material from the nuclear regions, since from the magnitude of the motions they do not appear to be gravitationally bound. P Cygni line profiles in stellar envelopes, with redshifted emission and blueshifted absorption, were taken to be evidence of outflowing winds. This is because of the idea that the material in front of the star can be identified by its absorption against the star while its spectra can be seen to be blueshifted by its outflowing motions towards us. By the same argument, inverse P Cygni profiles, where the motions of the emission and absorption spectra are reversed, have been interpreted as contraction. In yet other sources, asymmetric line profiles with substantial enhancements of one side of the line profile were kinematic evidence for shocked gas. This became even more convincing when combined with excitation arguments. In nearby systems, the observed Doppler motions in the radial direction have been found to be consistent with detectable PROPER MOTIONS across the line of sight. This is consistent with our expectation that the Earth is not an unique vantage point. After systematic motions are removed, the spectra often still exhibit nonthermal motions. That is to say, the line profiles are broader than can be explained by thermal motions alone. This has led to the studies of turbulence, especially with regard to the role of magnetic fields.

Measuring excitation

The various energy levels within the atom will be populated according to the ambient conditions such as temperature, particle density and radiation field. By sampling an appropriate set of transitions, we can construct the population distribution and thereby measure the excitation of the emitting source. In particular, it is easy to see that successively higher ionization states will require higher excitation, since the electrons will see a less shielded nucleus (see EXCITATION AND IONIZATION). Hence, if the detected radiation is dominated by lines from highly ionized atoms, we can deduce that the emitting

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

region must be ionized by energetic photons. The relative strengths of the various atomic lines are therefore a means to identify the spectral type of a star, in addition to its colors (see also CLASSIFICATION OF STELLAR SPECTRA). The relative line intensities also determine the hardness of the radiation. This has allowed us to distinguish between normal galactic nuclei, whose ionization can be easily explained by the radiation from young stars, and LINERS and Seyferts whose radiation field must be progressively harder. Another example of the power of spectroscopy was the identification of HERBIG–HARO objects as regions of shock excitation. Whereas these sources were once thought to be sites of young stars, spectroscopy showed otherwise. Together with proper motions and Doppler velocity measurements and line profiles, the relative intensities of the various ionized lines were consistent with shock models.

Measuring abundances

The detection of numerous atomic transitions allows the assessment of the abundances of the elements. With improved sensitivity, the abundances can be measured not only in the Sun and other stars but also in clouds and in external galaxies. Such data are crucial for checking NUCLEOSYNTHESIS models, for understanding the metal abundances as a function of time and as a gauge on evolution. For example, POPULATION I and POPULATION II stars can be distinguished based on their metallicity. Whether HIGH-VELOCITY CLOUDS in the Galaxy are primordial in nature or recycled from the disk of the Galaxy can also be determined by measuring the relative abundances of metals. Detailed measurements of the various elements in SUPERNOVA ejecta can also be used to classify the type of supernova event and also to check on elemental production mechanisms.

Important atomic lines

There are a number of atomic lines which are of particular interest. These include the Balmer lines in the optical, the Brackett lines in the near infrared, the radio recombination lines, the 21 cm atomic hydrogen line and the ionized carbon line in the far infrared. In general, the spectral lines from ionized hydrogen are important for tracing H II REGIONS. In particular, the infrared and radio lines are useful for studying deeply embedded sources.

Optical lines

The Lyman series of hydrogen, which consists of the recombination lines which end in the $n = 1$ state (where n is the total quantum number for Bohr–Sommerfeld orbits), is found at ultraviolet wavelengths. The Balmer series, the lines of which end in the $n = 2$ state, is found in the optical. The hydrogen lines together with lines from other elements have been used to classify the spectral types of stars. The temperature in the photosphere, as inferred from the type of lines which are excited, is an important part of the HERTZSPRUNG–RUSSELL DIAGRAM for stellar evolution. The Hα line at 6563 Å, which is the $n = 3$–2 Balmer line, has been one of the most useful lines in optical work, tracing regions which have been photoionized by a nearby star. This is particularly important in external galaxies because the nuclear regions are often highly ionized by a concentration of massive stars or an active nucleus powered by a BLACK HOLE. The bright nuclear emission in the Hα line can be used to measure the ionizing luminosity, the absolute motion of the gas from its redshift, which in turn yields a distance via the Hubble relation, and perhaps most importantly the nature of the nucleus from the observed line widths. The advent of SPECTROGRAPHS with high resolving power allows the astronomer to distinguish between narrow line widths consistent with galactic rotation and much wider line widths which may represent outflowing winds from the nuclear region. In the case of active nuclei powered by nonthermal processes, the radiation has a harder spectrum than ordinary starlight. Hence, lines from higher excitation states of hydrogen or rarer elements become detectable and even stronger sometimes. In the past decade, optical spectroscopy has made great progress because of the construction of large-aperture instruments such as the Keck telescopes and the launch of the Hubble telescope. The larger collecting area has meant that ever higher-redshift systems are being detected. The Hubble telescope with its superb imaging capability above the atmosphere has meant that spectroscopy can be done at under 0″.1 resolution. Some of the best evidence for the existence of massive black holes in the nuclei of galaxies has come from the Hubble measurements of very large rotational motions in the central few tenths of an arcsecond (see figure 1). For stellar work, one of the most important advances has been the development of spectrographs with tremendous resolving powers. Eschelle spectrographs are now able to resolve a line with a resolution of better than 100 000. By fitting many spectral lines at once, Doppler motions on the order of a few meters per second can be detected. This has allowed the development of the study of extrasolar planets, where planets in orbit around nearby stars are inferred from the reciprocal motions of the stars due to the gravitational pull from a secondary body. Some 20 planets have now been inferred from the Doppler motions of these wobbling stars (see EXOPLANETS).

Ultraviolet lines

Because the Lyman series lies in the ultraviolet, little progress was made until space-borne telescopes became available. With the Goddard High-Resolution Spectrograph on the Hubble Telescope, absorption lines can be measured for many atomic and molecular species. This has allowed the measurement of elemental abundances towards Galactic and extragalactic sources. In particular, metal abundances are important for identifying whether material is primordial in nature or has already been processed through star formation. Elemental abundances in interstellar clouds as measured in the gas phase can be compared with cosmic abundances in order to deduce the fraction of various elements which are locked up in dust

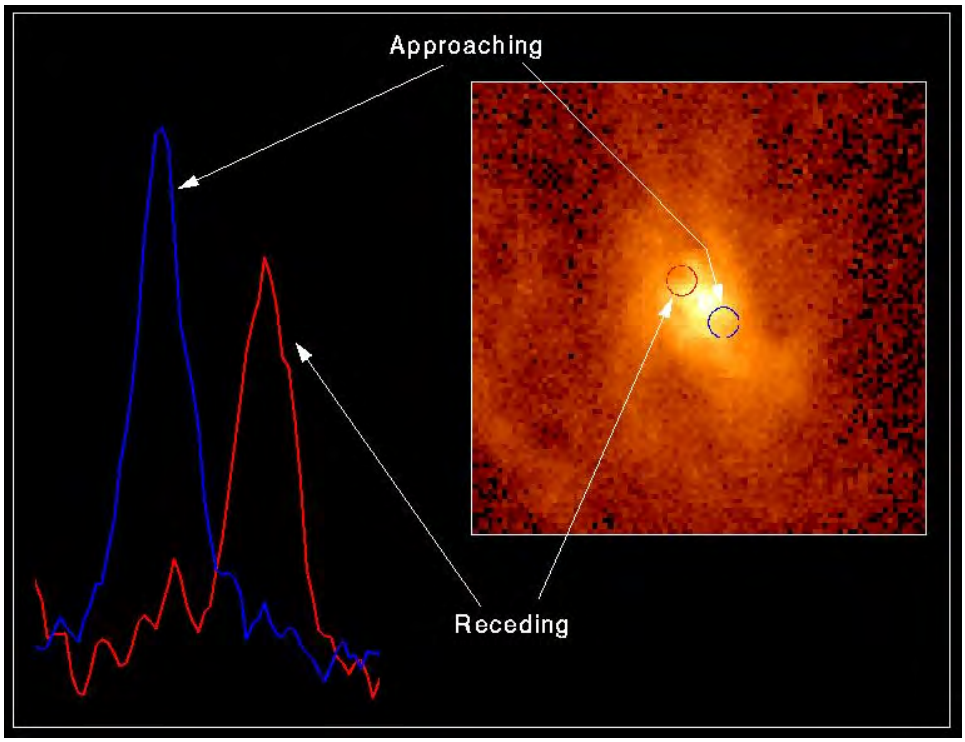

Figure 1. An image of the ionized disk surrounding the nucleus of M87 from the Hubble Space Telescope. Shown are two spectra of the O III emission line at 0″.25 offset on either side of the nucleus. The two spectra are redshifted and blueshifted by about 500 km s^{-1} over a size scale of about 35 pc. The implied enclosed binding mass is about 2 billion solar masses. Such motions, if bound, constitute some of the best evidence for massive black holes in the centers of galaxies.

grains. The measurement of the Lyman lines from deuterium can be compared with the corresponding hydrogen lines in order to estimate the deuterium fraction. This is of course a check on the synthesis of elements in the early universe since deuterium is not made through stellar nucleosynthesis. The deuterium fraction depends on the primordial baryon density during the first few minutes of the big bang. A higher baryon density would drive a faster rate for the formation of helium 4, which would tend to deplete the deuterium. The Ly α lines are also studied in absorption against quasars. Since there is a lot of intervening hydrogen gas on the way to distant quasars, all the Lyman absorption lines form a band of absorption on the blue side of the Lyman line which is intrinsic to the quasar system. This so-called LYMAN ALPHA FOREST has become an important tool to probe the intergalactic medium.

Infrared lines

While the Hα line and other optical lines have been very useful, they are susceptible to dust extinction effects. This is particularly bothersome for cores of molecular clouds where young stars are deeply embedded or for edge-on nuclear disks where the line-of-sight extinction can be many magnitudes in the optical wavelengths. One could compare the Hα and Hβ line intensities to estimate extinction effects. However, in practice, this is unreliable if both lines are suffering heavy extinction. Moreover, if the extinction is high enough, the Hα line may not be detectable at all. In the near infrared, the extinction due to dust is much reduced. As a result, the Brackett lines of hydrogen at 2 μm and 4 μm have been very useful for studying embedded sources both in the Galaxy and in external systems. In the mid-infrared, there are also fine-structure lines due to the spin–orbit interactions of the electrons, where there is an energy difference depending on whether the spin of the electron is aligned with the orbital angular momentum vector of the electron. For example, a particularly useful transition is due to the $^2P_{3/2}$–$^2P_{1/2}$ line for Ne II at 12.8 μm. This line has been successfully used to study H II regions, planetary nebulae, extragalactic nuclei and most famously the ionized gas streamers around the Galactic Center (see figure 2). Not only is the ionized gas detected to be in the form of streamers which orbit the Galactic Center but the kinematics is determined from the Ne II line profiles. Orbits fitted to the motions of the ionized gas suggest a central massive object with about three million solar masses.

With the development of more and more sensitive detectors as well as space-borne telescopes, the near-infrared window is becoming a very important diagnostic for external galaxies. The Infrared Space Observatory was able to detect and measure many atomic lines in the near

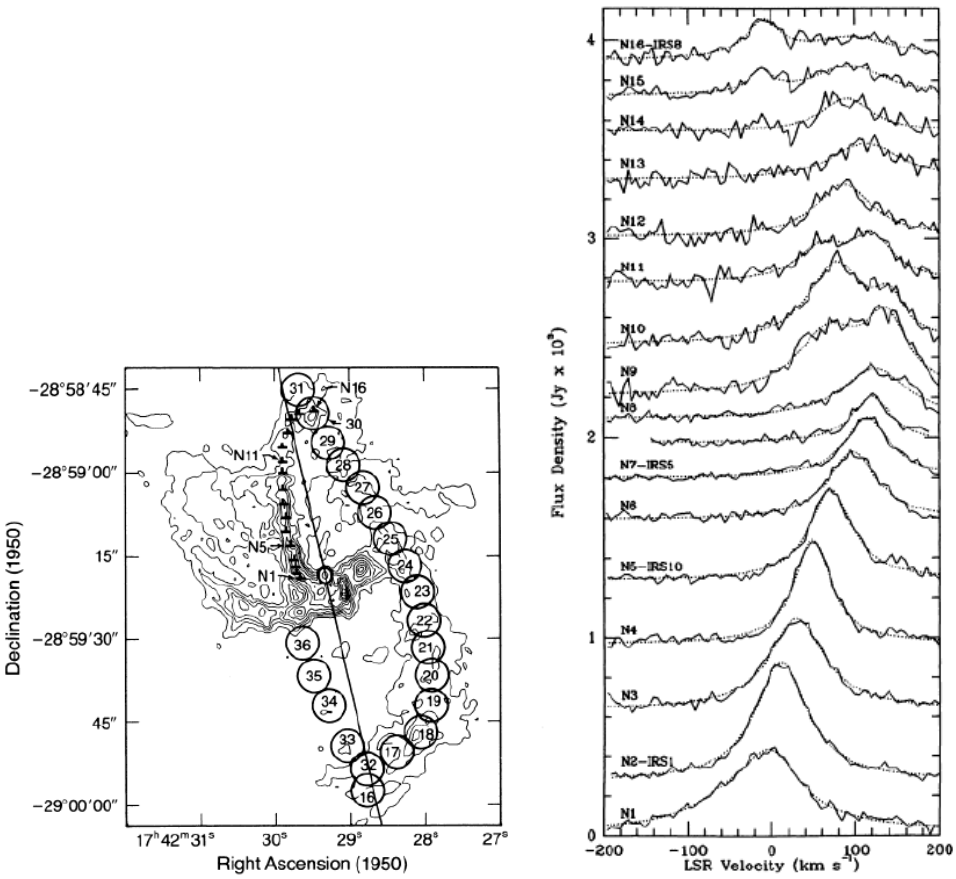

Figure 2. The left image is a picture of the ionized streamers detected in radio continuum toward the Galactic Center region. Overlaid are the positions where the Ne II 12.8 μm fine structure line emission has been measured. A number of ionized gas streamers can be seen to be in orbit around the central object known as SgrA*, a point-like radio continuum source. The right image is a display of the spectral profiles measured in the northern ionized arm. The kinematics of the Ne II emission has been fitted to orbital motions around SgrA*. This resulted in an estimate of $3 \times 10^6 M_\odot$ for the central mass if the motions are bound. These results are some of the best evidence for a massive black hole in the center of the Galaxy.

and mid-infrared toward many systems. These provide information on the chemical abundances and excitation (see figure 3) as well as on motions for these galaxies. Such information has been very useful for understanding whether the infrared-luminous galaxies can be driven by star formation processes alone.

Neutral atomic hydrogen

As 90% of the universe is in the form of hydrogen, it is clearly the most important atom. While the original identification of the Balmer series was necessarily in the optical, the Lyman series is in the ultraviolet, while the Paschen, Brackett and later series are in the infrared. All of these lines require a good deal of energy to excite, making them good tracers in stellar environments and in surrounding ionized regions. For the lower excitation regions, there is the 21 cm spin-flip line. This line originates in the interaction between the spins of the electron and the proton. The hydrogen atom has slightly more energy when the spins are parallel versus anti-parallel. The resulting photon on de-excitation comes out at a wavelength of 21 cm. The required excitation is so small that this line can be detected throughout the Galaxy and easily in external galaxies. Moreover, unlike optical lines, the 21 cm line is impervious to extinction effects. Hence the kinematic information from the line profiles can be traced throughout the entire Galaxy even though we are viewing the system edge on and within the disk. One of the first 21 cm results was the identification of a number of SPIRAL ARMS within the Galaxy, heretofore unseen. This 21 cm line has become a most important tool for studying galactic dynamics, interacting galaxies, cluster environment and redshifts in the nearby universe. One of the important features of the hydrogen line is that it can exist where stellar matter does not. Hence far out in the Galaxy, where matter is no longer dense enough to make stars, we can still trace the INTERSTELLAR MATTER. Studies at 21 cm have shown that often galaxies are several times larger in atomic hydrogen than their optical extents.

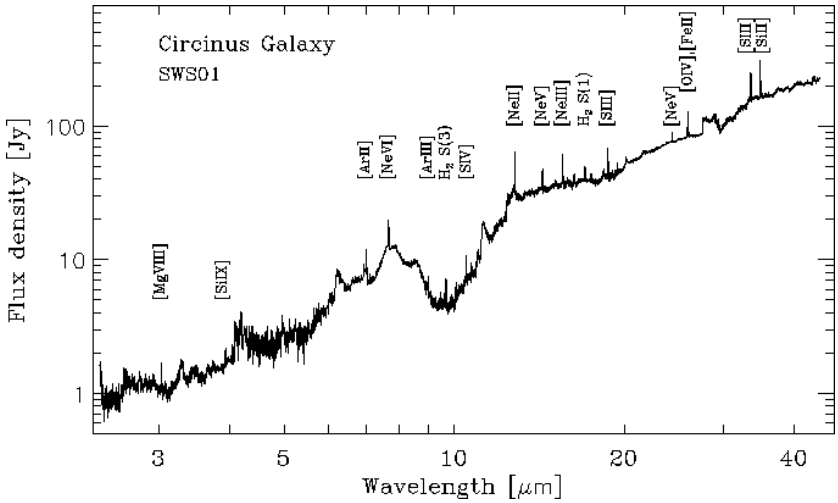

Figure 3. An infrared spectrum of the Circinus galaxy from the Infrared Space Observatory. A number of spectral features from atomic ions can be seen. The comparison of the relative intensities of these ionic features tells us the excitation state of the gas.

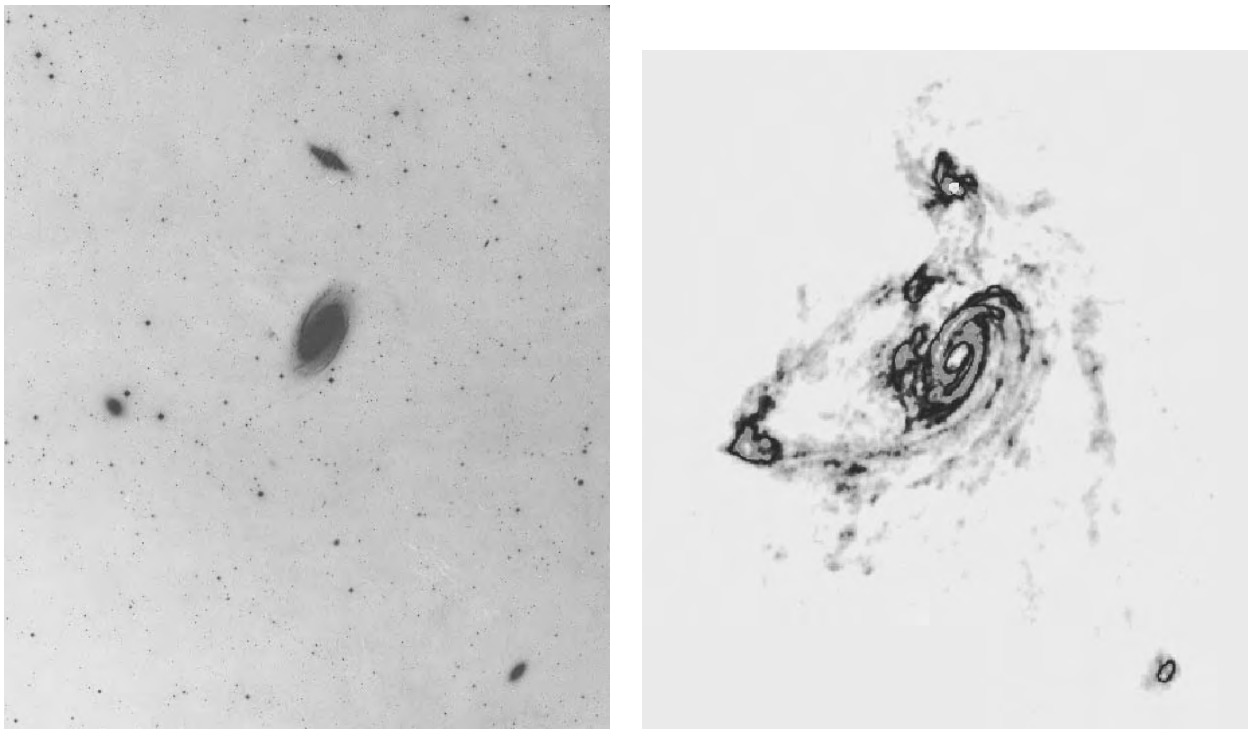

Figure 4. The left panel shows an optical picture of the M81–M82–NGC2077 group. The right panel shows an atomic hydrogen 21 cm line image of the same group of galaxies. The atomic hydrogen clearly shows a lot of material which is not seen in the optical and in particular shows that interactions among the three members of the group have resulted in tidal distortion of the gaseous disks of these galaxies.

There are two tremendously important effects which have been found. First, in SPIRAL GALAXIES, where we can see the rotational motions of the stars and the gas, it has been found that the rotation curve of the galaxy, when traced in atomic hydrogen, appears to be flat as far out as we can detect the hydrogen. The implication is that there is a lot of matter which is enclosed in the outer parts of the galaxy. Otherwise, the rotation curve will fall with increasing radius because of the decreasing gravitational effects of the enclosed mass with increasing distance. This is one of the key results suggesting the existence of DARK MATTER. If sufficient dark matter is there, it may have implications

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

for the question of whether the universe is open or closed, i.e. whether there is enough matter to bound the Hubble expansion of the universe. The second important result has been the detection of peculiar motions and structures in the outer parts of galaxies which can be attributed to interactions with nearby systems (see figure 4). Such interactions are typically not seen in the optical which traces the inner parts of the galaxy. This has implications for the dynamic nature of galaxy formation and evolution, as well as for the formation and fueling of massive black holes especially in interacting systems.

Radio and far-infrared lines

For hydrogen, the higher recombination lines, those ending in the higher n states, occur in the radio wavelengths. The main advantage of these lines is the absence of dust extinction at radio wavelengths, making the intensity of these lines a very accurate measure of the total ionizing luminosity. The main drawback for radio studies, the coarse angular resolution, was overcome by the development of RADIO INTERFEROMETERS. While the recombination lines at centimeter wavelengths can suffer from nonthermal excitation effects, the lines in the millimeter wavelengths in general are free from such effects and have line strengths nearly equal to the radio continuum emission from the H II regions. In the far infrared, there are a number of important lines. One of the interesting lines is the C II $^2P_{3/2}$–$^2P_{1/2}$ fine-structure line at 158 μm. This line is excited by collisions with H I and electrons in photodissociation and photon-dominated regions. It is an important coolant and has been estimated to carry as much as 0.5% of the total infrared luminosity of a galaxy. This C II line can therefore be an important tool for studying high-redshift systems where other lines may be too faint to detect.

Molecular lines

While a few molecules such as CN were detected via optical absorption lines, the floodgates to molecular astronomy did not open until the late 1960s. This was partially due to the necessary wait for the development of detector technology. However, there was also great skepticism that molecules could exist at all in the interstellar medium. This pessimism was based in part on the low gas density seen associated with atomic hydrogen clouds which implied that molecules would be dissociated by the ambient radiation fields. In hindsight, we can now assert that since stars form from gas, the gas must pass through a dense phase which is substantially denser than the atomic phase. Such a dense phase would of course provide shielding against interstellar radiation and would allow the formation of molecules. However, back in the 1960s, none of the theoretical underpinnings on STAR FORMATION, INTERSTELLAR CHEMISTRY or INTERSTELLAR MOLECULAR CLOUD evolution was in place. Persistence by a few radio astronomers led to the discovery of OH, H_2O, NH_3, CO and many other molecules.

Molecules

While atomic transitions typically fall within the optical wavelengths or the near infrared, molecular transitions are typically at much longer wavelengths. This is due to the fact that, for molecules, rotational and vibrational motions of the atoms within the molecule are also possible. These provide new sets of quantized energy states. Transitions between rotational states typically fall into the radio wavelengths, and vibrational transitions are typically in the infrared. While atomic transitions are characterized by temperatures on the order of thousands of kelvins, molecular transitions require temperatures of tens to hundreds of kelvins. The molecules are therefore good probes for the bulk of the universe which is cool with temperatures near 10 K. Since the early detection of the key molecules of H_2O and NH_3 in the late 1960s, and of CO in the early 1970s, over 110 molecular species have now been identified in the interstellar medium. The availability of molecular transitions with different excitation requirements allows the study of the interstellar medium under a wide combination of temperatures and densities. In particular, transitions with high dipole moments have been used successfully to study the very dense regions of molecular clouds which are forming stars. With the tremendous improvement of detector technology at radio wavelengths, and the construction of large-aperture telescopes, molecules are now easily detected in external galaxies. Perhaps the most important results have been the discovery and realization that molecular clouds are a dominant constituent of the interstellar medium, that molecular lines along with dust are important coolants for the gas phase and that molecules can trace the mass, the temperature, the density and the motions of the interstellar medium.

Instrumentation developments

Progress in the field of spectroscopy of atoms and molecules in astronomy has come about through a number of technological innovations. Grating spectroscopy with finer and finer resolution has been developed. Whereas long-slit spectroscopy can obtain spectra for a slice of the sky, the trend today is towards multifiber spectroscopy. In this scheme, hundreds of optical fibers are positioned at once on predetermined target sources in the focal plane. The fibers are then fed to a spectrometer in order to measure the spectra for hundreds of sources simultaneously. At radio wavelengths, interferometry with spectroscopy is even more powerful in that the entire primary beam of one of the telescope elements of the array is imaged at once. With the development of powerful digital CORRELATORS, large spectral bandwidths can be analyzed for every pixel in the primary beam. Compensation for atmospheric effects is also making good progress. Space-borne platforms and high-flying aircraft and balloons have opened up new spectral windows. ADAPTIVE OPTICS at optical wavelengths and self-calibration techniques at radio wavelengths have successfully compensated for atmospheric SEEING effects.

This has meant that spectroscopy of fainter sources is possible. Of course, detector technology has improved for all the wavelengths, while larger and larger telescopes are being built. These efforts have made tremendous improvements in sensitivity.

Astronomical Unit

The semi-major axis of the elliptical orbit of the Earth. The astronomical unit (abbreviation: AU), is also described as the 'mean' distance between the Earth and the Sun, where 'mean' in this context refers to the average of the maximum (aphelion) and minimum (perihelion) distances between the Earth and the Sun. The currently accepted value for the astronomical unit is 149 597 870 km.

An alternative definition is the radius of the circular orbit in which a body of negligible mass, if free of perturbations, would revolve round the Sun in a period of $2\pi/k$ days, where k is the Gaussian gravitational constant (=0.017 202 098 95).

Astronomische Gesellschaft

The AG was founded in 1863 in Leipzig as an international society dedicated to the 'advancement of science by means of supporting projects which require systematic cooperations of many people'.

The primary activities of the AG are the organization of scientific meetings and conferences, the promotion of young astronomers, awarding of medals and prizes in recognition of outstanding scientific works, awarding of honorary membership, the publication of scientific literature, the fostering of public relations, and the promotion of astronomical education at schools and of the general public.

At present the AG has more than 800 members.

Astronomy

The science of the universe, its constituent bodies and phenomena. Arguably the oldest of the sciences, its beginnings go back to the dawn of recorded history, to the time when mankind first began seriously to study the apparent motions of the Sun, Moon and planets and to identify patterns and cycles in their behavior. Astronomy found practical application in providing the basis for calendars, timekeeping and navigation, but is now essentially a pure science.

Astronomy is primarily an observational science rather than an experimental one. Whereas in physics or chemistry, for example, it is possible to set up experiments under controlled conditions, to change those conditions and measure the outcomes, in astronomy, apart from using satellites and spacecraft to explore our immediate locality, it is not possible to carry out experiments on stars and galaxies. Instead, astronomers mainly rely on collecting and interpreting information that arrives from astronomical sources in the form of electromagnetic radiation and particles in order to formulate and test hypotheses and theories. Ground-based astronomy is hampered by the atmosphere, which—even under ideal conditions—transmits to ground level only a small fraction of the complete range of electromagnetic radiations (the electromagnetic spectrum). Until the middle of the twentieth century, astronomy was carried out almost exclusively at visible (optical) wavelengths. Since then, ground-based astronomers have extended their observations into the radio and infrared regions of the spectrum (only limited quantities of infrared radiation reach ground level) and to the detection of particle radiations (neutrinos and cosmic rays). During the past four decades or so, with advances in space technology, astronomers have been able to explore planets and the interplanetary medium directly with the aid of spacecraft and, most significantly, to place instruments in orbit above the atmosphere, thereby gaining access to virtually the entire electromagnetic spectrum from gamma rays to radio waves.

In a few cases, astronomers can handle samples of cosmic material—neutrinos, meteorites, interstellar particles, Moon material, soon (possibly) dark matter astroparticles. Gravitational waves are also in the future of astronomy.

The fundamental types of observation that astronomers can carry out include astrometry (the measurement of positions and motions), photometry (the measurement of brightness and brightness changes), imaging and spectroscopy (the detailed analysis of the spectrum of radiation arriving from an astronomical source).

Astronomy and Astrophysics in India

Jayant Narlikar

The growth in astronomy and astrophysics (A&A) in India has been mostly since the country achieved independence in 1947. The present work is carried out in a few select research institutes and in some university departments. The Astronomical Society of India has around 300 working A&A scientists as members, with another 50–60 graduate students.

Facilities

In the institutional sector, the major facilities include the Vainu Bappu Optical Telescope of 2.3 m diameter and a 1 m telescope at Kavalur in South India, under the management of the Indian Institute of Astrophysics (IIA) at Bangalore, a 1 m telescope at the Uttar Pradesh State Observatory (UPSO) at Naini Tal in the foothills of the Himalayas and a 1 m infrared telescope at Gurushikhar in southern Rajasthan under the management of the Physical Research Laboratory (PRL), Ahmedabad. Solar telescopes exist in Kodaikanal in southern India, at the UPSO in Naini Tal and in Udaipur, the first being managed by the IIA and the third by PRL.

In the 1960s radio astronomy entered in a big way with a 550 m parabolic cylindrical antenna being set up on a north–south hill slope near the southern hill resort at Ooty, the axis of the cylinder being parallel to that of the Earth. This telescope is operated by the TATA INSTITUTE OF FUNDAMENTAL RESEARCH (TIFR), in Mumbai, which now has just completed an even more ambitious project known as the Giant Metrewave Radio Telescope (GMRT) at Khodad, about 90 km from Pune. Controlled and operated by its NATIONAL CENTRE FOR RADIO ASTROPHYSICS (NCRA) at Pune, this system has 30 antennas, each of 45 m diameter, spread over a Y- shaped array of arms about 14 km long. It works optimally at meter wavelengths. At lower frequencies (34.5 MHz), there is a T-shaped radio array at Gauribidnur near Bangalore operated jointly by the IIA and the Raman Research Institute (RRI), Bangalore. Indian astronomers have erected a similar array in the island of Mauritius. The RRI also has a 10 m dish for millimeter wave astronomy at its headquarters in Bangalore.

Space astronomy in India began with cosmic ray research under H J Bhabha at TIFR and later under V A Sarabhai at PRL. A national balloon facility at Hyderabad caters to the various balloon borne experiments. This activity blossomed into a fully fledged space program which now routinely launches satellites and prepares payloads of a commercial as well as a scientific nature. Its headquarters are at the Indian Space Research Organization at Bangalore.

In the university sector, the only significant working facility is the 1.2 m telescope at the Japal Rangapur Observatory under the control of Osmania University, Hyderabad. A major resource facility for the universities was, however, set up in 1988 by the University Grants Commission (UGC), New Delhi, at Pune. Known as the Inter-University Centre for Astronomy and Astrophysics (IUCAA), this center provides an excellent resource library in A&A, an advanced computer centre with A&A-related software, a data centre and an instrumentation laboratory. These facilities can be used by visiting academics and students from universities with their travel funding met by grants provided by the UGC at IUCAA. The IUCAA also assists university academics in using observing facilities in India and abroad under the various guest observing programs.

There are three new optical telescopes under various stages of construction. The IUCAA will have a 2 m telescope near Giravali, about 70 km from Pune, whereas the IIA has recently built a 2 m telescope at Han Le, at a height of 4000 m near Ladakh in the northern Himalayas. The UPSO and TIFR are jointly planning to set up a 3 m telescope in Devasthal, near Naini Tal.

Research areas

INDIAN ASTRONOMY has traditionally been working in stellar astronomy and spectroscopy, solar and planetary astronomy. However, in the last three decades of the 20th century it has expanded its range to include solar physics including solar oscillations, pulsar astronomy and modelling, problems in cosmic ray and high-energy astrophysics, gravitational lensing, extragalactic astronomy and cosmology. The Ooty Telescope was responsible for a major survey of angular sizes of radio sources through the lunar occultation method. Theoretical cosmology has ranged from abstract mathetical models in general relativity (for India has always had a strong school in general relativity) to fitting models to observations of discrete extragalactic source populations. Thanks to a less rigid outlook towards alternatives to mainstream ideas, these have flourished in India more than they have in the West.

Indian astronomy has made its presence felt internationally. The late Vainu BAPPU was President of the International Astronomical Union, while several Indian astronomers have occupied positions of Presidents of various IAU Commissions.

Astrophysical Bounds on Particle Properties

Ever since NEWTON proposed that the Moon on its orbit follows the same laws of motion as an apple falling from a tree, the heavens have been a favorite laboratory for testing the fundamental laws of physics, notably Newton's and EINSTEIN's theories of gravity. More recently, astrophysics and cosmology have become crucial testing grounds for the microcosm of elementary particles. This area of scientific inquiry is part of a discipline often called astroparticle physics or particle astrophysics. There are a few important cases where unexplained astrophysical phenomena can be attributed to new elementary particles or new properties of known particles; the solar neutrino deficit and the dark matter problem are cases in point. Here, another widespread method will be discussed, where one uses established properties of stars or even the universe at large to constrain possible modifications caused by novel properties of elementary particles.

Neutrino masses

One of the earliest astrophysical particle limits is the cosmological bound on the masses of the three known NEUTRINOS, the electron, muon and tau neutrino ν_e, ν_μ and ν_τ. The main idea is that these particles, in spite of their weak interactions, must have been thermally produced in the hot and dense early universe and thus form a 'cosmic neutrino sea', much like the 3 K cosmic microwave background radiation. A detailed calculation reveals a present-day density of neutrinos plus antineutrinos of about 113 cm^{-3} for each of the three 'flavors' ν_e, ν_μ and ν_τ, to be compared with about 400 cm^{-3} microwave photons. All of the neutrino masses must obey $m_\nu \lesssim 40$ eV or else their gravitational effect would have slowed down the expansion of the universe below its observed rate. It was the discovery of ν_μ in 1962, together with the 1963 discovery of the cosmic microwave background, that inspired S S Gershtein and Ya B ZELDOVICH to advance this argument in 1966.

The direct experimental m_ν limits are much less restrictive than the cosmological bound except for ν_e (figure 1), and it is not known if neutrinos have masses at all. However, much evidence for 'neutrino flavor oscillations' has accrued from measurements of atmospheric and solar neutrinos, implying that they do have masses, and that the mass differences between them are extremely tiny, smaller than about 0.1 eV. In any case, neutrino masses appear to be much smaller than those of the other fundamental fermions, the electron and its two heavier brothers (muon and tau) as well as the six quarks (figure 1). The origin of this mass spectrum remains a mystery of elementary particle physics.

The cosmological m_ν limit represents a standard argument to constrain the properties of any theoretically proposed new particles such as monopoles, axions or supersymmetric particles. Their contribution to the cosmic mass density must be compatible with the age

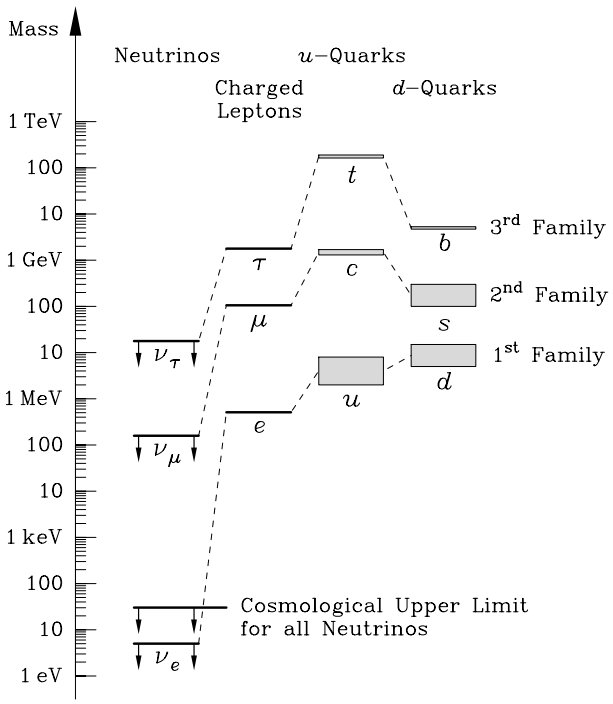

Figure 1. Mass spectrum of the elementary fermions. The vertical box size for the quarks indicates the mass uncertainty. For the neutrinos, the experimental upper limits are shown as well as the cosmological bound.

and expansion rate of the present-day universe. Usually, their relic density, the particle density surviving from the early universe, is more complicated to evaluate than for neutrinos where it simply scales with the density of cosmic microwave photons. In general, one has to worry about the detailed primordial production mechanism and annihilation rate of the new particles.

A completely different astrophysical method to constrain neutrino masses relies on the time-of-flight from a pulsed source. Neutrinos of mass m_ν which are emitted from a source at distance D at time $t = 0$, but with different energies E_ν, arrive at

$$t = \frac{D}{c\sqrt{1 - (m_\nu c^2/E_\nu)^2}} \qquad (1)$$

where $E_\nu \geq m_\nu c^2$ is the total energy including the rest mass and c is the speed of light. They are delayed because they move slower than c. Measuring their arrival times and energies allows one, in principle, to extract m_ν. A type II supernova (SN), the collapse of a massive star, produces a huge neutrino burst, lasting for a few seconds. Such an event has been measured once on 23 February 1987 when the electron antineutrinos from SN 1987A in the LARGE MAGELLANIC CLOUD ($D \approx 50$ kpc $= 163\,000$ light years) were registered in three neutrino detectors that were operational at that time (figure 2). The signal is compatible with the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

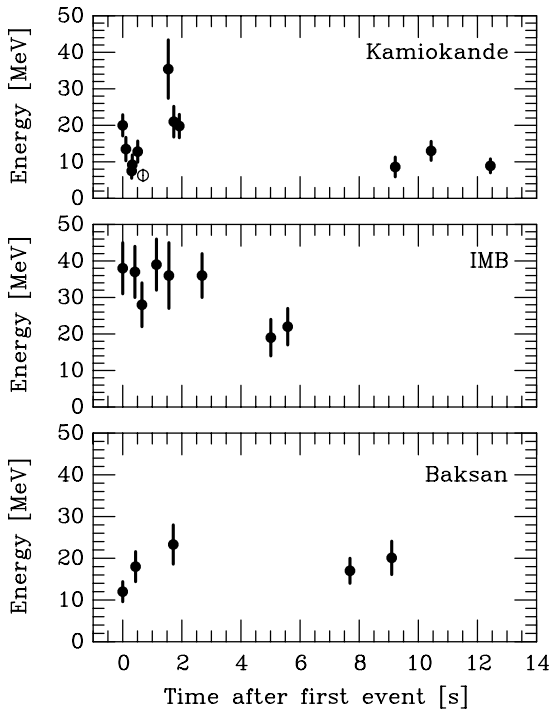

Figure 2. Neutrino signal from supernova 1987A at the Kamiokande, IMB and Baksan detectors. The clocks have unknown relative offsets; in each case the first event was shifted to $t = 0$. The Kamiokande event marked with an open circle is attributed to background.

expected intrinsic burst duration, with no evidence for time-of-flight dispersion, leading to a limit $m_{\nu_e} \lesssim 20$ eV.

Supernovas in or near our own galaxy are rare, perhaps a few per century. However, if one were lucky to observe another neutrino burst with one of the much larger detectors available today, one could improve the m_ν limits, even on ν_μ and ν_τ which are more difficult to detect. With the upcoming large 'neutrino telescopes' one may be able to measure neutrino pulses from more speculative sources such as gamma-ray bursts, with a potentially much better m_ν sensitivity.

Big-bang nucleosynthesis

Another standard cosmological argument is based on the expansion rate of the early universe at the epoch of primordial NUCLEOSYNTHESIS, about 3 min after the big bang. The radiation density at that time determines the expansion rate, which in turn influences the abundance of primordial helium which is observed to be 22–25% by mass, the remainder being hydrogen and traces of deuterium, helium-3 and lithium-7. Within their uncertainties, the observed primordial light-element abundances imply a radiation density corresponding to two to four families of neutrinos, nicely bracketing the three known flavors ν_e, ν_μ and ν_τ. These are the only possible families because additional ones would contribute to the decay width of the Z^0 gauge boson, which has been precisely measured since about 1990.

However, the big-bang nucleosynthesis method of counting neutrino families can be applied to more exotic particles that are not covered by the Z^0 decay-width argument. Any form of radiation which has been thermally excited in the early universe contributes to the expansion rate. Therefore, the interaction strength and masses of any proposed new particles must pass the test that they do not lead to excessive cosmic mass-energy density at the nucleosynthesis epoch.

Photon mass

In contrast with neutrinos which are expected to have masses, photons should be strictly massless, a theoretical expectation that requires experimental verification. Time-of-flight limits from the radio signal of pulsars are not much better than about 10^{-11} eV, the plasma frequency of the interstellar medium which mimics a photon mass. Laboratory tests of Coulomb's law give $m_\gamma \lesssim 10^{-14}$ eV; a non-vanishing m_γ would modify the inverse-square behavior. Likewise, the spatial variation of higher-multipole terms of large-scale magnetic fields give 0.6×10^{-15} eV and 0.8×10^{-15} eV from Jupiter's and Earth's magnetic fields respectively. The most restrictive limit of 10^{-27} eV is based on the magneto-gravitational equilibrium of the gas in the SMALL MAGELLANIC CLOUD which requires that the range of the interaction exceeds the characteristic field scale of about 3 kpc. This limit is surprisingly close to 10^{-33} eV where the photon Compton wavelength would exceed the radius of the observable universe and thus would cease to have any observable consequences.

Stellar energy loss

A particularly successful astrophysical argument to constrain the properties of low-mass, weakly interacting particles, notably neutrinos, goes back to J Bernstein, M Ruderman and G Feinberg (1963). They argued that a putative neutrino magnetic dipole moment would lead to an unacceptably large energy loss of stars by virtue of the plasma process $\gamma \rightarrow \nu\bar{\nu}$ which is kinematically allowed because the plasma frequency in the interior of a star gives photons effectively a mass. This energy-loss channel would add to the emission of neutrinos from the interior of stars by standard processes.

A non-standard energy-loss channel, caused by the emission of neutrinos with non-standard couplings or the emission of hypothetical particles such as axions, could cause a variety of observable effects. Stellar remnants (WHITE DWARFS, NEUTRON STARS) would cool faster. Normal stars would consume their nuclear fuel faster and thus burn out earlier. The helium-burning lifetime of horizontal-branch stars as measured by number counts in globular clusters has been a particularly precise measure of novel energy-loss channels. Likewise, a possible delay of helium ignition by particle cooling of red-giant cores can be well constrained by the observed brightness limit of the tip

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the red-giant branch in globular clusters. Even our Sun provides interesting constraints. An increased burning rate would make it more evolved than corresponds to its age, causing observable shifts of its precisely measured p-mode oscillation frequencies, a field of research known as helioseismology.

Arguments of this sort have been applied to a great variety of cases; perhaps the most useful limit is the constraint $\mu_\nu \lesssim 3 \times 10^{-12}\mu_B$ on a magnetic dipole moment of any neutrino. Here, $\mu_B = e\hbar/2m_e$, with e the electron charge and m_e the electron mass, is the Bohr magneton, corresponding to the electron's magnetic moment, which is usually employed as a measure for possible neutrino magnetic moments. Laboratory experiments give much weaker limits.

Likewise, one can derive a limit on a hypothetical neutrino electric charge, $e_\nu \lesssim 2 \times 10^{-14}e$, applicable to all flavors. For the measured electron antineutrinos from SN 1987A, the galactic magnetic field would have caused an energy-dependent deflection and thus a time-of-flight signal dispersion; the resulting limit is $e_{\nu_e} \leq 3 \times 10^{-17}e$. A laboratory limit, based on charge conservation in β decay, is $e_{\nu_e} \lesssim 3 \times 10^{-21}e$.

If neutrinos have masses they may decay; one possible channel is by the emission of a photon. The absence of anomalous x- or gamma-ray fluxes from the Sun or in conjunction with the SN 1987A neutrino burst as well as limits on a spectral deformation of the black-body nature of the cosmic microwave background constrain this radiative decay channel. However, the matrix element of this process depends on an electromagnetic transition moment which is subject to the above stellar energy-loss constraint; it is more restrictive for $m_\nu \lesssim 1$ eV than the direct limits on decay photons.

Supernova 1987A

The SUPERNOVA 1987A neutrino signal (figure 2) allowed for a particularly useful application of the stellar-energy loss argument. The nascent neutron star that has formed after collapse cools by neutrino emission over several seconds, a time scale which is set by the neutrino diffusion rate; a proto neutron star is so hot and dense that even neutrinos cannot freely escape. A competing cooling channel by more weakly interacting particles which are not trapped would shorten and weaken the neutrino signal because the total amount of energy, the gravitational binding energy of the neutron star, is fixed.

This simple argument has been applied to many cases, but perhaps the most interesting one is that of axions, hypothetical low-mass particles that were originally proposed in the context of quantum chromodynamics, the theory of the strong interaction among quarks. It was later recognized that axions are also a good particle candidate for the dark matter of the universe. Axion models are essentially characterized by one free parameter which can be chosen to be their mass m_a. The requirement that axions do not carry away the bulk of the SN 1987A energy translates into a limit $m_a \lesssim 10^{-2}$ eV. On the other hand, the requirement that their cosmic mass density is not too large leads to $m_a \gtrsim 10^{-5}$ eV, in contrast with the above case of neutrinos where cosmology provides an upper mass limit. In the remaining mass range, axions could well exist and provide most or all of the cosmic dark matter.

Strange stars

The fundamental constituents of nuclear matter are quarks, not protons and neutrons, and one may well wonder if neutron stars do not undergo a phase transition to a medium consisting of free quarks. Even the strange quark is relatively light (figure 1) so that one may speculate that 'neutron stars', the remnants of massive stars after a type II supernova collapse, are actually 'strange stars', consisting of a strongly interacting medium of up (u), down (d) and strange (s) quarks. It is surprisingly difficult to distinguish the two cases observationally. It is thought that strange stars can rotate faster before breaking apart so that sub-millisecond pulsars, if they were ever detected, could perhaps resolve the question of the ground state of nuclear matter.

In summary, astrophysics and cosmology provide important constraints on the properties and interactions of elementary particles which are often complementary to what can be measured in laboratory experiments.

Astrophysical Institute, Potsdam

Built upon a tradition of almost 300 years, the Astrophysical Institute Potsdam (AIP) is in an historical sense the successor of one of the oldest astronomical observatories in Germany. It is the first institute in the world which incorporated the term 'astrophysical' in its name, and is connected with distinguished scientists such as Karl Schwarzschild and Albert Einstein. The AIP constitutes one of the four centers of astrophysical research in Germany and is the largest astronomical institute in the new states of Germany. The cooperation with the University of Potsdam is of utmost importance.

The bodies responsible for AIP are the Ministry for Science, Research and Culture of the State of Brandenburg and the Federal Ministry for Education, Science, Research and Technology. The AIP is an institute of the 'Wissenschaftsgemeinschaft Gottfried Wilhelm Leibniz'.

The AIP concentrates its efforts on two main avenues of research: cosmic magnetic fields, solar and stellar activity (Bereich I); and extragalactic astrophysics and cosmology (Bereich II).

Within a German consortium the AIP is part of the international 'LARGE BINOCULAR TELESCOPE' (LBT) to be built in Arizona by 2004 and contributes to the operation of the German solar telescopes on Tenerife.

The main site of the institute is the Sternwarte Babelsberg. The Solar Observatory Einstein Tower at the Telegrafenberg in Potsdam and the Observatory for Solar Radio Astronomy in Tremsdorf near Potsdam are branches of the institute.

Astrophysical Jets

There are many circumstances in astronomy when gas is found to circulate around a central gravitating mass. This happens in BINARY STARS, where one component is a compact object—white dwarf, neutron star or black hole—and mass is transferred from the normal stellar companion. It happens in the nuclei of galaxies, where the gravitating object is a massive black hole and it also happens during the earliest phases of evolution of a protostar. These gas flows are called ACCRETION DISKS and they are frequently accompanied by rapid outflows, launched in antiparallel directions, roughly perpendicular to the disks. The outflows are usually called jets and this article describes some of what we know about them.

The first example of an astrophysical jet was discovered by HEBER CURTIS in 1918 using the Lick Observatory in California. He observed the galaxy known as M87 in the Virgo cluster of galaxies and, when he inspected the nucleus, he found a 'curious straight ray... apparently connected with the nucleus by a thin line of matter'. This was a remarkable observation (by a remarkable astronomer), and the jet in M87 is still one of the most carefully studied of this class of objects (figure 1).

What we observe directly in M87 is a fairly straight feature, some 2 kpc in length. It can be seen from long radio wavelengths to high-energy x-rays and is found to exhibit about eight regions of high intensity, known as 'knots', along its length. The jet can be traced down to a scale size of order 0.01 pc which is smaller than 10^{-5} times its total length and less than 100 times the radius of the black hole that has been found to lie in the nucleus of M87, and whose mass is measured to be about 3 billion solar masses (see M87: THE NUCLEUS AND JET.

We know that the gas is flowing away from the black hole in M87 because we can use very long baseline interferometry to measure its speed. What is found is that some parts of the jet appear to be moving outward with a speed that appears to be as much as six times faster than the speed of light. This is actually quite a common phenomenon called superluminal expansion. It does not violate the special theory of relativity (which stipulates that all material motion occurs slower than the speed of light). Instead, superluminal expansion is an illusion which only requires that the gas in the jet moves towards us with a speed close to that of light. For this reason, jets like that in M87 are often styled relativistic jets. It is quite natural that these jets move with speeds close to that of light; after all this is the escape velocity from the central black hole.

The jet in M87 exhibits another common property of these objects in that its antiparallel counter jet, which is expected to be present, has not yet been detected. This is an illustration of an effect called ABERRATION. When a source of radiation moves at near light speed, it will appear to beam its emission along its direction of motion. Consequently, if the source happens to be approaching us, then it will appear to be very bright, whereas, if the source moves away from us, it will appear to be faint. This explains why we are only able to detect one jet in M87 and why a high proportion of the brightest sources that we see exhibit SUPERLUMINAL MOTION.

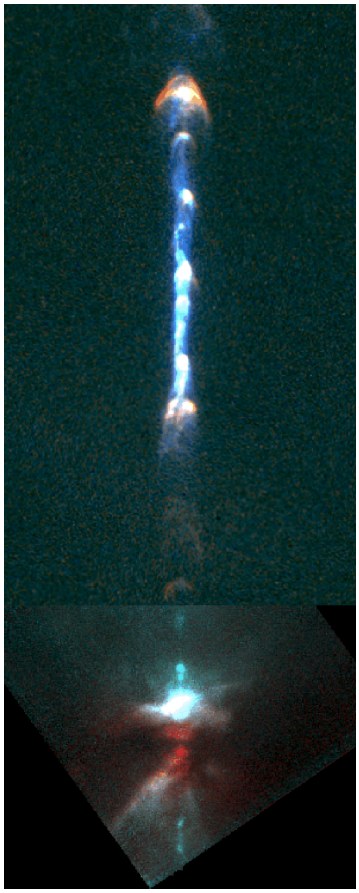

Figure 2. HH 111. Protostellar jets emerging from a young star—one member of a triple system observed using Hubble Space Telescope. The jets are over 10 light years in length. The bright knots are probably associated with shock waves formed when faster moving gas runs into slower gas.

Let us now turn to the knots. These are believed to be shock waves formed in the outflowing jets when, for example, the jet speed at the source increases by an amount greater than the speed of sound in the jet and therefore faster than the speed with which information can be transmitted by the moving jet fluid. A strong shock discontinuity must eventually form in the flow and this turns out to be an excellent site for accelerating high-energy, relativistic electrons with energies up to 100 TeV. These electrons radiate by spiralling in the magnetic field that permeates the jet—a process known as SYNCHROTRON RADIATION—and this is thought to be responsible for the entire radio through x-ray emission.

M87's jet is relatively weak. We know so much about it because it is so close. In the past, it was almost surely supplied with gaseous fuel at a far higher rate than at

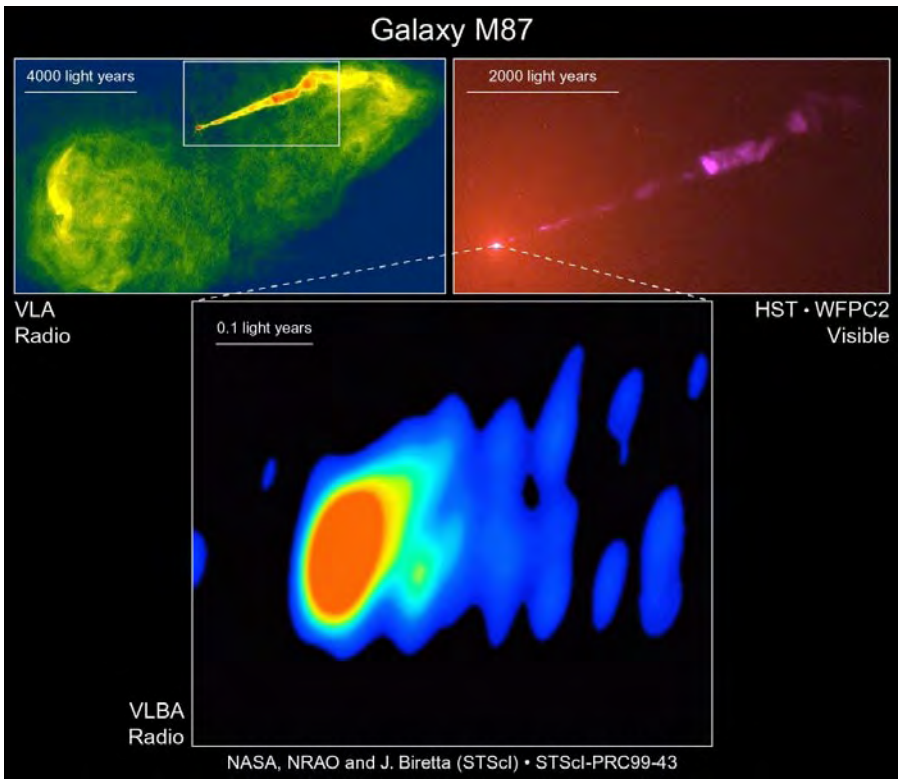

Figure 1. Radio and optical maps of the jet observed emerging from the nucleus of the nearby elliptical galaxy M87. The jet can be traced down to a distance smaller than 100 times the size of the central black hole.

present. It would then have been classified as a QUASAR. Quasars are the hyperactive nuclei of very distant galaxies that can outshine their stellar hosts at optical wavelengths. They emit prodigiously throughout the electromagnetic spectrum. Quasars often exhibit giant, double, radio sources—two 'lobes' of intense radio emission located on opposite sides of the galaxy. Historically, this was the way in which quasars were originally identified. For a long while there was a mystery as to how these radio lobes could be formed and sustained. With the discovery of relativistic jets, the mystery was solved. The source of their power is the central black hole and the accretion disk that surrounds it. This creates relativistic particles and magnetic field which flow outward, along two antiparallel directions to replenish the radio lobes and to propel them away from the galaxy, rather like the exhausts that are associated with automobiles and jet aircraft. In some sense, the jets carry away the waste products of accretion onto a black hole. We know of thousands of these double radio sources and have documented their properties so that we are beginning to understand how they fit into an evolutionary sequence.

The most powerful relativistic jets, that are beamed almost directly at us, are sometimes called BLAZARS and these are commonly observed as γ-ray sources. Photons, with energies as high as several GeV, are formed when an x-ray photon is scattered by a relativistic electron—a process known as inverse Compton scattering. (In a few local examples, it has been possible to detect very-high-energy γ-rays with TeV energies that are probably produced close to the central black hole.) The surprisingly large intensity of these γ-ray jets tells us that, in many instances, they are transporting away a large fraction of the total power generated by the central black hole engines.

Not all jets are associated with distant galaxies. There are many stellar-sized black holes that have been found in our Galaxy and in nearby galaxies. When these have stellar companions that can lose gas, the gas will be attracted by the black hole and can also form an accretion disk. An early example was the source SS433 where two precessing antiparallel jets moving with speed just over a quarter the speed of light have been found. In some instances, these sources also produce relativistic jets, small-scale versions of the extragalactic radio sources. They exhibit giant outbursts, superluminal expansion and beaming and, as a result, are sometimes called 'microquasars'. These are particularly good to study because astronomers can observe many cycles of variation in the time it takes a quasar to change.

Jets have also been found associated with newly formed stars. Here, again there is an orbiting disk made of the gas that has not yet settled onto the star (or condensed into planets), These 'YOUNG STELLAR OBJECTS' are observed primarily in optical and infrared emission lines and the jet moves with speeds of several hundred

km per second which is comparable with the escape velocity from the central protostar. These jets sometimes also exhibit moving shock waves known as Herbig–Haro objects (figure 2), which propagate along the length of the jets. (As the jet speeds are much less than the speed of light, there is neither superluminal motion nor aberration in this case.) It is almost likely that similar basic physical processes are at work here too. These 'protostellar jets' are particularly good to study because the flow velocities can be measured accurately using spectral lines.

The nature of the mechanism for the formation and collimation of jets is still a matter of controversy. Many astronomers believe that strong magnetic fields are generated in the accretion disk and that these are responsible for launching and focusing the outflow. Most of the jet power probably derives from close to the central object, black hole, neutron star, white dwarf or protostar, also through the agency of magnetic field. Computer simulations of magnetized gas flows around central gravitating bodies are starting to give some insight into how and why jets are such a frequent companion to accretion disks.

Astrophysics

That branch of astronomy concerned with the physics of, and physical processes operating in, stars and other celestial bodies. It may be argued that the subject of astrophysics really began with the development of spectroscopy in the nineteenth century. Today astrophysics has transformed cosmology, the study of the evolution of the universe, from an almost purely speculative activity to a modern science capable of predictions that can be tested.

Astrophysics to 1900

In practice, there is no clear dividing line between astrophysics and astronomy. The former is usually defined as the study of the physical properties of celestial objects, whereas the latter is concerned with their positions and motions. However, the two types of measurement are often linked. For example, stellar mass—a physical property—is typically measured by observing the orbits of two stars round each other. However, it was evident from the start that the equipment used and knowledge required for the two types of activity were different. During the latter part of the 19th century, as the subject began to develop rapidly, it was therefore recognized as a distinct field of study, although it took some time before 'astrophysics' became the accepted name. At the time, astrophysical measurements were as often described in terms of 'celestial chemistry' as 'celestial physics'. Because such observations differed from traditional positional measurements, astrophysics was also, on occasion, called the 'new astronomy'. (To add to the confusion, studies of motion were sometimes referred to as 'physical astronomy'.) These contemporary terms will be ignored here: relevant work will simply be called 'astrophysical'.

Early astrophysical observations

Some physical properties of celestial bodies can be determined by direct observation through a telescope. From this viewpoint, observations of astrophysical significance date back to the invention of the telescope in the early 17th century. Prior to this there had been speculation—for example, that stars were bodies like the Sun—but little by way of firm evidence. Several of GALILEO's observations in 1610, with his newly invented astronomical telescope, proved to have physical implications. One was his discovery that lunar topography bears some resemblance to the Earth's (the first step towards the lunar geology of the space age). The most important of his observations for subsequent astrophysics was his discovery of SUNSPOTS. Apart from recording the complex, changing nature of sunspots, Galileo also used them to show that the Sun, like the Earth, was rotating on its axis. Later in the 17th century, another of Galileo's discoveries—the moons of Jupiter (see JUPITER: SATELLITES)—led to the first determination of the velocity of light. RØMER, working at the newly established Paris Observatory, found that the times at which the moons appeared and disappeared behind Jupiter seemed to vary systematically. He attributed this to changes in the Earth–Jupiter distance, together with a finite speed of light. Rømer's measurements provide an early example of the fact that, although the study of astrophysics mostly entails astronomers relying on developments in physics, they have sometimes been able to contribute something in return.

In the latter part of the 17th century, NEWTON examined the way in which sunlight, after passing through a prism, was spread out into its constituent colours. Such spectroscopic observation was to become the most significant part of astrophysics, but only after some delay. In 1800, W Herschel in England repeated Newton's experiment (see HERSCHEL FAMILY), but with the new aim of measuring the heating power of different parts of the solar spectrum. The thermometer he used recorded the existence of considerable heating beyond the red end of the visible spectrum. This was the first identification of infrared radiation (although, as is often the case with important advances, Herschel interpreted it differently). It was paralleled in the following year by the first detection of ultraviolet radiation. Ritter in Germany, inspired by Herschel's work, investigated the action of the solar spectrum on silver chloride. He found that maximum breakdown of the chemical occurred beyond the violet end of the visible spectrum. (This was an early step on the way to photography.) A year later still, in 1802, Wollaston, who was also studying the solar spectrum back in England, found that it was crossed by a few dark lines. He thought that these simply represented demarcation points where the various spectral colours began and ended. It was left to Fraunhofer in Germany, a decade later, to discover that the whole of the solar spectrum was intersected by dark lines. He detected nearly 600 of these; so, hardly surprisingly, they came to be referred to as 'FRAUNHOFER' LINES.

The solar spectrum

As this rush of discoveries suggests, it was an interest in the Sun, and, more especially, in the solar spectrum, that primarily triggered the 19th century growth of astrophysics. There were various reasons for this interest. One was that the Sun was an excellent light source. As compared with other light sources, whether celestial or in the laboratory, the Sun produced copious amounts of light. Consequently, even highly inefficient optical equipment could yield results. Another reason was the particular interest that early 19th century scientists had in color phenomena. The solar spectrum provided the easiest way of studying these.

Laboratory investigations showed that different substances produced different sets of spectral lines. So there was a tendency from early on to suppose that the Fraunhofer lines could be related to chemical substances on the Earth. However, this supposition was not fully confirmed until the second half of the 19th century. There were many problems to resolve first. For example, it was found that some Fraunhofer lines did not originate on the Sun at all, but were impressed on the sunlight during its passage through the Earth's atmosphere. More fundamentally, laboratory spectra consisted of bright, not dark, lines. How were the two connected? In 1849, FOUCAULT finally managed to show the identity of lines appearing in emission and absorption. To do this, he experimented with the pair of lines in the solar spectrum that Fraunhofer had labeled 'D', because they were particularly intense. However, these same lines were also responsible for retarding attempts to interpret

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

spectra. The difficulty was that the D lines appeared to be ubiquitous in the laboratory. Whatever substance was being studied, they always seemed to appear. It was only in the 1850s that the widespread contamination of laboratory chemicals by salt—leading to the appearance of the sodium D lines—was fully recognized.

All this clearing of the ground had to occur before the solar spectrum could be properly interpreted. The final step in this process can be seen as the key event in the foundation of astrophysics. It was taken by KIRCHHOFF, working in conjunction with his Heidelberg colleague, Bunsen, in the period around 1860. Their studies actually began in the laboratory with the invention of the Bunsen burner. Bunsen intended to apply the non-luminous flame this produced to studying the colours emitted by different elements when they were burnt. For this purpose, he proposed to use a set of color filters. Kirchhoff suggested Bunsen should use a prism instead, and this led to a comparison with the solar spectrum.

Kirchhoff established two basic principles for the analysis of spectra. The first was that incandescent solids or liquids give continuous spectra, but gases produce lines or bands (the positions of which depend on the particular gas present). The second was that, when a source of continuous spectrum is viewed through a cooler gas, the wavelengths at which absorption occurs correspond to those at which emission occurs when the gas is heated. The immediate implications for the Sun were similarly twofold. Firstly, the body of the Sun must consist of hot dense material to produce the observed continuous spectrum. Secondly, the absorption lines produced in the cooler solar atmosphere can be used to study the chemical composition of the Sun.

Although it was a study of the atmospheric lines that dominated subsequent 19th century astrophysics, Kirchhoff's conclusion regarding the body of the Sun had an immediate impact on contemporary thought. The picture of the Sun widely held in the first half of the 19th century saw the sunspots as holes in a luminous cloud, through which a colder interior could be viewed. Indeed, W Herschel speculated that the solar interior, visualized as having a solid surface, might even be inhabited. Kirchhoff's spectrum analysis showed that such a picture was impossible.

Other solar studies

By this time, another problem concerning the Sun had arisen. The first half of the 19th century saw the first significant attempts to measure the amount of heat reaching us from the Sun. Such measurements of what came to be called the 'SOLAR CONSTANT' provided a quantitative estimate of the vast amount of energy being emitted by the Sun. At about the same time, the idea of the conservation of energy began to establish itself. So the question arose—where does the Sun obtain its energy? It was clear that chemical sources would only keep the Sun burning for a very short time, so some physical source was necessary. The solution that came to be widely accepted during the second half of the 19th century was put forward by HELMHOLTZ in 1854. He suggested that the Sun gained its heat from gravitational contraction. The rate required was well below the observational limit, and the process was capable of sustaining the Sun's output for several million years. This lifetime seemed reasonable to physical scientists, but it came under increasing attack from geologists and biologists. They thought—correctly, as it turned out—that the evolution of the Earth's surface and its inhabitants required a much longer span of time.

One further characteristic of the Sun became the focus of attention in the mid-19th century. This was its changing activity. In the early 1840s, SCHWABE, a German amateur astronomer, found from his counts of sunspots that the number visible on the Sun's disc varied periodically with time. His conclusion was publicized a few years later by HUMBOLDT, at a time when a number of studies were being made of fluctuations in the Earth's magnetic field. In 1852, SABINE in England pointed out that these magnetic fluctuations varied with a period that coincided with the sunspot cycle. This conclusion was soon confirmed and extended by others and led to a continuing interest in solar–terrestrial relations throughout the second half of the 19th century.

The major features of the Sun's atmosphere had already been discerned before Kirchhoff became interested in the solar spectrum. Since the solar atmosphere was too faint to be seen in the presence of full sunlight, its characteristics had had to be examined during solar ECLIPSES. Expeditions to eclipses in 1842 and 1851 had shown that the Sun's surface was surmounted by a CHROMOSPHERE (so called because of its red color). Above this stretched a much thinner CORONA. Extending into this from the chromosphere were large 'flames' (later called 'prominences'). Kirchhoff's explanation of the solar spectrum now opened the way for a more detailed examination of the atmospheric structure.

The first astrophysical advance was made in 1868. In that year, a solar eclipse was visible from India, and one of the observers—the Frenchman, JANSSEN—looked at the spectra of prominences. He and others found bright lines, showing that prominences were clouds of gas. Janssen concluded that the lines were so bright that they should be visible out of eclipse. He subsequently scanned the solar limb and showed that this was, indeed, the case. At the same time, LOCKYER in England made spectroscopic observations of the Sun and observed the same lines. This meant that both the chromosphere and the prominences could be mapped at the solar limb, without requiring an eclipse. Because the cornona was so faint, it continued to be observable only at eclipses throughout the 19th century. At the 1869 eclipse, the first bright coronal line was found. It was now evident that the emission lines of both the chromosphere and the corona differed significantly from the absorption spectrum of the Sun. From Kirchhoff's work, this meant that neither could be the source of the Fraunhofer lines. At the 1870 eclipse, the American astronomer, YOUNG, showed that the absorption

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

lines were actually produced in a restricted region—which was labeled the 'reversing layer'—between the chromosphere and the apparent surface of the Sun.

The explanation of the bright solar surface also developed further in the 1860s. At the end of that decade, Andrews in England showed that gases at a high enough temperature could not be liquified. This confirmed what was already suspected: that the body of the Sun must consist of gas under high pressure, rather than of liquid as Kirchhoff had supposed. This raised a new question—why did the Sun appear to have a clearly defined surface (labeled the photosphere) at all? It was generally agreed that the photosphere must represent the level in the Sun where the gases became sufficiently cool for refractory materials to condense out. The renewed belief in a cloudy solar surface remained in vogue until the early 20th century.

Thus, within the space of a few years, spectroscopic observations had provided a reasonably clear picture of the Sun's atmosphere. The next few decades were spent in sorting out some of the uncertainties in this picture. One related to chemical composition. Following Kirchhoff, a number of observers compared terrestrial spectra with the solar spectrum in an attempt to determine the chemical composition of the Sun. It was found that almost all the elements that could be detected were metals (although hydrogen was noted early on). However, it proved impossible to identify one very bright line in the chromospheric spectrum. Lockyer suggested that this was produced by a new element, consequently called 'helium', which had not yet been found on Earth. This suggestion was strongly contested, but Lockyer was vindicated in the 1890s when Ramsay discovered the gas, via its spectrum, in terrestrial rocks. It was similarly found to be impossible to identify the coronal lines. The parallel suggestion was therefore made that they were due to a new element, labeled 'coronium'. In this case, no corresponding element was ever found. (It was not until near the middle of the 20th century that the coronal lines were shown to be due to known elements in highly ionized states.)

Stellar astrophysics

In the early days of astrophysics, the Sun was such a popular target for observation that the whole subject was sometimes simply called 'solar physics'. This overlooked the fact that Kirchhoff's findings were also immediately applied to observations of stellar spectra. It was soon apparent that stellar spectra could differ greatly from each other. So, together with investigating stellar chemical composition, it was also necessary to explore the possibility of classifying stars into groups. This was pursued in the 1860s primarily by the Jesuit astronomer, SECCHI. After examining a few thousand stars, he came to the conclusion that they could all be placed into four groups, depending on the appearance of their spectra. It was noted that these spectral types were correlated with the colors of the stars—white, yellow or red. During the same period, HUGGINS in England used higher-dispersion spectra to look for chemical constituents. Despite the differences between the spectra, he found that many lines could be identified with elements found on the Earth and the Sun.

In these early days, stellar spectra—like the solar spectrum—were observed visually. Whereas the Sun produced adequate light, this was not true of stars. The obvious answer was to use photography, but the 'wet plate' process in vogue in the 1860s was insufficiently sensitive. It was not until the end of the 1870s, when the 'dry plate' process became available, that the photography of stellar spectra became feasible. New discoveries then followed quickly. An important one derived from the fact that the photographic plates were more sensitive than the human eye in the ultraviolet, with the result that a number of new lines were detected in that region. Huggins in England and VOGEL in Germany found lines there which they believed extended the sequence of hydrogen lines found in the visible. A study of the wavelengths of these lines led the Swiss, BALMER, to announce the numerical formula for the wavelengths of hydrogen lines now called after him. His success encouraged the idea that spectral lines are produced by related sequences of atomic vibrations. Photographic recording of stellar spectra also allowed the first reasonably accurate radial velocities to be measured. This led to the discovery of spectroscopic binaries: the first found—Mizar—was detected by Miss Maury at Harvard towards the end of the 1880s.

Stars and nebulae

Photography also ultimately helped with another type of astrophysical measurement—stellar brightness. During the 1880s, E C PICKERING at Harvard and Pritchard at Oxford produced photometric catalogs of the brighter stars in the Northern hemisphere based on visual estimates of brightness. They were extended to Southern hemisphere stars in the early 1890s by Bailey observing in Peru. It was generally believed by this time that photographic photometry would be the way forward in the future. Unfortunately, it proved difficult to reach agreement on how to reduce the photographic images to equivalent magnitudes (and it was only slowly realized that photographic and visual magnitudes could differ considerably, depending on the color of the star). Consequently, photographic photometry had only contributed to a minor extent by the end of the 19th century.

By the latter years of the century, photography—particularly the Harvard survey work—was proving a valuable way of picking up variable stars. Interest in the visual observation of variables, originally stressed by Argelander in Germany, had grown from the mid-century onwards. The system of designating variable stars via letters of the alphabet was already in use by the 1880s, and exemplars of the main types of variable were under investigation by the end of the century. The ones that attracted most attention were the NOVAE (supernovae were not distinguished as a separate category until the 20th

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

century). Huggins, in 1866, was the first to examine the spectrum of a nova. He found that it consisted of an ordinary stellar absorption spectrum with superimposed bright lines. Both this and later novae spectra were therefore interpreted as indicating the explosion of a cloud of gas from a stellar body.

During the 1860s, Huggins undertook a survey of the spectra of bright nebulae. (In the 19th century, a 'nebula' meant any extended patch of light, as compared with stars, which were point sources.) Ever since W Herschel's time, there had been a debate concerning the nature of nebulae. Were they some kind of fluid, or stars clustered so close together that they could not be resolved? The first object Huggins examined was a PLANETARY NEBULA. It showed a bright line spectrum, which was immediately interpreted as meaning that nebulae were gas clouds. The problem was that some of the spectral lines could not be linked to any known terrestrial elements. It was therefore suggested, by analogy with helium, that a new element—'nebulium'—was present. Although the idea remained in play for the rest of the century, nebulium, like coronium, ultimately proved to be spurious. The bright lines were shown in the 20th century to be due to oxygen in a rarified state.

As more spectra of nebulae were observed, the initial conclusion concerning their nature became more questionable. Planetary nebulae and what were called 'irregular' nebulae (of which the Orion nebula was a prime example) always gave emission lines. However, other nebulae (a key example being the Andromeda nebula) gave spectra that appeared to be continuous, without either dark or bright lines. The interpretation of this kind of spectrum was a matter of dispute for the rest of the century. The first hint of the way forward did not come until 1899, when SCHEINER in Germany found faint traces of absorption lines on a long-exposure photograph of the spectrum of the Andromeda nebula. Direct photography had by this time provided some further information on this latter type of nebula. Lord ROSSE, observing in Ireland in the 1840s, had discerned visually that a few nebulae seemed to have a spiral structure. When sensitive photographic plates became available towards the end of the century, it was shown—particularly by KEELER in the United States—that many more spiral nebulae existed. It was natural to suppose that the unusual spectrum and the unusual shape of such nebulae were linked.

At the end of the 18th century, the French mathematician, LAPLACE, had suggested a way in which the solar system might have formed. He envisaged a contracting nebula, which spun more rapidly as it shrank. The spin rate finally reached a point where material was ejected in rings round the equator. This material subsequently condensed into planets, with the final central condensation forming the Sun. The picture painted by this 'nebular hypothesis' suggested that the contracting material would look very like a spiral nebula. So it came to be thought that such nebulae were simply nearby planetary systems in the process of forming.

In 1885, the confusion was added to by the appearance of a new star—actually a supernova—in the Andromeda nebula. This was naturally equated to other new stars—ordinary novae—observed in the Milky Way during the 19th century. The corresponding misestimate of distance suggested that the Andromeda nebula was part of our own Galaxy. Another contributory factor was the distribution of the spiral nebulae. It became apparent that these did not occur near the plane of the Milky Way (the so-called 'zone of avoidance'). Although the cause was not known (subsequently found to be due to obscuring dust in the Milky Way), this distribution suggested that the nebulae were linked to our Galaxy. At the beginning of the century, the idea that many nebulae were clusters of stars, some equal to our own Milky Way in extent, had been widely debated. By the end of the century, most believed the universe to be dominated by the Milky Way.

Stellar evolution

By this time, a lively interest was developing in stellar evolution. It was inevitable, once different categories of stars had been established, to ask how the groupings related to each other. The contemporary concern with evolution in geology and biology naturally encouraged a search for relationships that were evolutionary in nature. The first widely held view, developed particularly by Zöllner and Vogel in Germany, was that stars formed a single evolutionary sequence. They were born hot and white in color. As they dissipated their heat, they became successively yellow and then red. There was a problem here. The only physical mechanism known to drive change was contraction. Both Lane in the USA and Ritter in Germany showed that a contracting sphere would actually heat up, rather than cool. However, their results assumed that a star was a sphere of perfect gas. No-one at the time thought that such a model could represent a real star.

By the end of the century, evidence was beginning to accumulate that stars of the same color could differ appreciably in other characteristics, such as size. The most radical revision to the 19th century picture of stellar evolution—Lockyer's 'meteoritic hypothesis', proposed in the 1880s—assumed that this was the case. Lockyer suggested that stars formed from nebulae that consisted of clouds of meteorites (popular objects of study in the latter part of the century). Contraction of the nebula led to an increased rate of collision between its constituent meteorites, and so raised its temperature. The nebula, now visible as a star, gradually changed its color from red, through yellow, to white. By the time this latter point had been reached, all the meteorites had been vaporized. The white star therefore now cooled down, becoming smaller as it went back through the sequence from yellow to red. Unlike other schemes, Lockyer's hypothesis thus supposed that red stars fell into two categories—either very large, or very small.

Interpreting spectra

Lockyer based his arguments on a comparison of the spectra of meteorites in the laboratory with spectra from a wide range of stars. Some of this work came under attack, and his hypothesis was not widely supported. Nevertheless, detailed studies of stellar spectra became increasingly a topic of interest. In the mid-1880s, E C Pickering at Harvard initiated a large-scale investigation of stellar spectroscopy and photometry. The first results appeared in the 1890s as the Draper memorial catalog of stellar spectra. (Draper was a pioneering US astrophysicist, whose family provided money for the project subsequent to his death.) The catalog introduced the alphabetical classification of stellar spectra still in use today. The spectra used for classification purposes at Harvard were too small scale for detailed study, but Miss Maury examined a subset of the stars in greater detail. She found that stars of the same color could still have subtle differences in the appearance of their spectra. She speculated that these might have implications for stellar evolution. (Indeed, her work led onto Hertzsprung's distinction between giant and dwarf stars in the early years of the 20th century.)

The basic problem was that the theoretical understanding of spectra remained fairly primitive throughout the 19th century. The difficulty was that, not only were the spectra often complex in themselves, but, even worse, they could change according to the light source. For example, the laboratory spectrum of an element produced with an electric arc could have some lines different from a spectrum of the same element produced with an electric spark. One proposed explanation was that elements could be broken down to an extent that varied according to the conditions to which they were subjected. This suggestion met considerable opposition, not least because it had been a basic tenet of 19th century science that atoms were indestructible.

Unfortunately, Lockyer, who was the strongest supporter of this argument, initially held a mistaken idea of what was happening. It had been noted early on that laboratory spectra from different elements often had some lines coincident in position. Locker called them 'basic' lines and believed that they revealed the presence of a common breakdown product from the initial elements. As higher-dispersion spectroscopes became available, it was found that these basic lines were simply close to each other in position, rather than coincident. Consequently, they possessed no fundamental significance. Towards the end of the century, Lockyer was influenced by his assistant, A FOWLER, to alter his ideas about the breakdown of elements. Attention was now called to another group of lines—labeled 'enhanced' lines—which varied from source to source. These lines were, indeed, associated with what would now be called ionized atoms. However, Lockyer's contemporaries were mostly so confused by his reinterpretation that the new idea received little initial attention. By this time—the end of the century—evidence was beginning to accumulate that atoms could be broken down. J J Thomson's work on the electron is a key example of this. Detailed understanding of astronomical spectra had to await the development of quantum theory in the 20th century.

In trying to interpret spectra, the Sun remained the prime source of comparison data throughout the 19th century. For example, the spectra of sunspots were found to have bands similar to those found in the spectra of red stars. Since sunspots were believed to be cooler than the Sun as a whole, this fitted in well with expectations regarding stellar temperatures. The problem lay in actually putting a figure to the temperatures involved. A white star might be hotter than a red star, but how much hotter? Again, it was hoped to answer this question first for the Sun. Ways of linking the temperature of a body to the radiation it emitted were limited in the mid-19th century. They mostly depended either on Newton's law or on Dulong and Petit's law, but these gave widely differing results. For example, one estimate in 1860 suggested the solar surface was at some 7 000 000 °C, whereas another in 1872 suggested 1400 °C. Of the various proposed revisions, the one that ultimately proved most useful was put forward by Stefan in 1879. His suggestion of a dependence on the fourth power of the temperature had no theoretical backing until the development of quantum theory. It was therefore treated with some reserve in the 19th century.

The development of astrophysics

In 1859, a solar FLARE was observed for the first time. It was intense enough to be visible in white light against the Sun's disc and was accompanied by a major magnetic storm and widespread AURORAE on Earth. The difficulty was that such events were normally invisible, since instrumental limitations meant that most solar observing was done at limb. This changed in the 1890s, when HALE in the USA (and also DESLANDRES in France) introduced the idea of viewing the entire Sun in the light of a single line, so allowing solar activity to be scanned across the disc. This development well illustrates the continuing link between new astrophysical research and better instrumentation. By the end of the century, not only was an increasing diversity of equipment being hung on the end of telescopes: the telescopes, themselves, were undergoing change. Thus, the fact that photographic plates were sensitive to a different region of the spectrum from the human eye meant that refracting telescopes for photographic use had to be specially designed and adjusted. Furthermore, the need for the maximum possible light grasp led to a growing interest in the use of reflecting telescopes for astrophysical research.

In its early years, many astronomers regarded astrophysics as an inferior adjunct to classical astronomy. It was less rigorous, not requiring the grounding in mathematics essential for classical astronomy. Despite attempts to link solar activity with terrestrial weather, it had less practical outcome than classical astronomy, which was the traditional basis for terrestrial measurement of time and position. Above all, it had no satisfactory theory to integrate it all together. Hardly surprisingly, many of the pioneer

astrophysicists were amateurs, or came from other disciplines. Yet, within a few decades, astrophysics had become a subject in its own right: by the 1890s a major journal—the *Astrophysical Journal*—was already devoted to it (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS). Significantly, this was launched in the United States. North America had played only a minor role in the development of classical astronomy. As the new century dawned, it was widely accepted in the astronomical world that it would play a much greater part in the development of astrophysics.

Atacama Large Millimeter Array

The Atacama Large Millimeter Array (ALMA) will be the largest aperture synthesis telescope, operating at millimeter and submillimeter wavelengths, ever constructed. It is to be built on the plateau close to Cerro Chajnantor in the eastern Atacama desert of northern Chile, at an altitude of 5000 m. The project is being developed by an international consortium, which currently includes the US and nine European countries, and should be ready for scientific use in 2009.

The project is the natural successor to existing millimeter-wave interferometers at IRAM, OVRO, BIMA and Nobeyama. It will have 64 12 m diameter antennas, and will operate at wavelengths from 5–0.35 mm, allowing it to map at high resolution the molecular gas and dust in nearby star-forming regions, and star-forming galaxies at high redshift.

Atmospheric Pressure

The pressure (i.e. the force per unit area) exerted on the surface of a planet by the weight of gas contained in a column extending vertically upwards to the limit of the atmosphere. At the surface of the Earth, the average value of atmospheric pressure, in SI units, is 1.013×10^5 pascal (Pa), where one pascal is equivalent to a force of one newton per square meter (N m^{-2}). A further unit of pressure is the bar, which is equivalent to 10^5 pascal, a common submultiple of which is the millibar (mb); 1 millibar $=$ 0.001 bar. A pressure of 1.013×10^5 Pa is equivalent to 1.103 bar, or 1013 millibars. The average value of atmospheric pressure at the surface of the Earth (1013 mbar) is also referred to as 1 atmosphere. By way of comparison, the atmospheric pressures at the surfaces of Venus and Mars are, respectively, 90 and 0.006 atmospheres.

Atmospheric refraction

Rays of light entering the Earth's atmosphere (i.e. passing from the vacuum of space to the medium of air) are bent, or refracted. As a result of this, the apparent positions of the stars are displaced by a small amount towards the zenith. In other words, the effect of atmospheric refraction is to increase the apparent altitudes of stars. At relatively small values of zenith distance, the effect is small, and is proportional to the tangent of the zenith distance. However, at large zenith distances, the effects are quite appreciable. At the horizon (zenith distance = 90°) refraction increases apparent altitudes by about 35 arc minutes. This means, for example, that at the moment that the lower edge of the Sun appears to touch the horizon at sunset, the whole disk of the Sun is actually below the horizon.

Atom

The smallest particle of a chemical element that retains the properties of that element. Each atom consists of a compact nucleus, in which all but a tiny fraction of its total mass resides, surrounded by a cloud of electrons—lightweight particles with negative electrical charge. A typical atomic nucleus has a radius of about 10^{-14} m; the overall radius of an atom (i.e. the radius of its cloud of electrons) is about 10 000 times larger (about 10^{-10} m). The nucleus consists of a number of protons (massive particles with positive electrical charge) together with a number of neutrons (particles of similar mass to the proton but with zero electrical charge), all of these particles being bound together by the strong nuclear interaction. The surrounding cloud of negatively charged electrons is held around the positively charged nucleus by the electromagnetic force. A complete (neutral) atom contains the same number of protons as electrons and, because it has equal numbers of positively and negatively charged particles, has zero net charge. An atom that has lost one or more of its electrons and which, therefore, has a net positive charge, is called a positive ion. An atom that has acquired one or more extra electrons and which, therefore, has a net negative charge, is called a negative ion.

Each element is assigned a chemical symbol that takes the form of a letter or a pair of letters; for example, hydrogen is denoted by H, helium by He, and so on. An atom is characterized by its atomic number (denoted by the symbol Z), which is the number of protons in its nucleus, and by its mass number (A), which is the total number of protons and neutrons contained in its nucleus. Conventionally, an element is denoted by its chemical symbol, preceded by mass number as a superscript and its atomic number as a subscript. Thus, an element, X, with atomic number Z and mass number A, would be written as ${}^{A}_{Z}\mathrm{X}$. For example, a normal hydrogen atom with one proton and no neutrons in its nucleus ($Z = 1$; $A = 1$) would be denoted by ${}^{1}_{1}\mathrm{H}$; a helium nucleus with two protons ($Z = 2$) and two neutrons ($A = 2 + 2 = 4$) would be denoted by ${}^{4}_{2}\mathrm{He}$, and so on. Atomic number defines the chemical element of which a particular atom is an example. Thus, for example, every hydrogen atom has $Z = 1$, every helium atom has $Z = 2$, and so on. Nuclei of the same chemical element may, however, contain different numbers of neutrons. Atoms that have the same number of protons but different numbers of neutrons, in their nuclei, and which, therefore, have the same atomic number but different mass numbers, are called isotopes. For example, 'heavy hydrogen', or deuterium, denoted by ${}^{2}_{1}\mathrm{H}$ (or ${}^{2}\mathrm{D}$) is an isotope of hydrogen that has one proton and one neutron, rather than just a single proton, in its nucleus. Helium exists in two forms, helium-4 (${}^{4}_{2}\mathrm{He}$) and helium-3 (${}^{3}_{2}\mathrm{He}$), a lighter isotope with two protons but only one neutron in its nucleus. The average of the various naturally occurring isotopes of a particular element, weighted according to their relative abundances, is the atomic weight of that element.

Although quantum mechanics has shown that electrons in atoms cannot be regarded strictly as points localized in space and that the electron clouds surrounding a nucleus represent regions where the probability of finding electrons is highest, the Bohr model of the hydrogen atom, which was proposed in 1913 by the Danish physicist Neils Bohr (1885–1962), continues to provide a good basis for describing the way in which atoms emit and absorb radiation. According to this model, a hydrogen atom consists of a single proton around which a single electron travels in one of a number of permitted orbits, each of which corresponds to a different energy level. If the electron drops down from a higher level to a lower one (makes a 'downwards transition'), it emits a photon (a quantity of radiant energy) with an energy equal to the difference in energy between the upper and lower levels. The wavelength of the emitted radiation is inversely proportional to the energy of the photon (the greater the difference in energy levels, the shorter the wavelength of the emitted radiation). Conversely, if an electron absorbs a quantity of energy equal in magnitude to the energy difference between a lower and a higher level, it will jump up to the higher level (makes an 'upward transition'). The emission and absorption of radiation that occurs when electrons make downward and upward transitions between the various energy levels of hydrogen atoms gives rise to the series of emission or absorption lines that constitutes the hydrogen spectrum. With more massive atoms, which have numerous electrons arranged in concentric shells, the set of energy levels and permitted transitions is more complex, but the same general principle applies: downward transitions give rise to the emission of radiation and upward transitions occur when energy is absorbed.

Auriga

(the Charioteer; abbrev. Aur, gen. Aurigae; area 657 sq. deg.) A northern constellation that lies between Perseus and Gemini, and culminates at midnight in early December. It is usually said to represent Erichthonius, legendary king of Athens and inventor of the four-horse chariot who was raised by the goddess Athene, and is shown on early celestial charts as a charioteer supporting a goat and its two kids on his left arm. Its brightest star, α Aurigae (Capella), is known as the 'little she-goat', and two of its other naked-eye stars, η Aurigae and ζ Aurigae, as 'the kids'. The brighter stars of Auriga were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large, conspicuous constellation, Auriga is easily recognized by virtue of Capella, which at magnitude 0.1 is the sixth brightest star in the sky and from northern temperate latitudes is almost immediately overhead on winter evenings. Other bright stars include β Aurigae (Menkalinan), an eclipsing binary (range 1.9–2.0, period 3.96 days), ε Aurigae, a remarkable eclipsing binary (range 3.0–3.8, period 27.1 years—the longest of any such star) and ζ Aurigae, yet another eclipsing binary (range 3.7–4.0, period 972 days). There are six other stars of magnitude 4.0 or brighter. The star Elnath, magnitude 1.7, was originally designated γ Aurigae, but has been reallocated to the neighboring constellation of Taurus (as β Tauri).

The Milky Way passes through the south-western part of Auriga and the constellation contains several open star clusters, including M36 (NGC 1960), which contains about 60 stars between ninth and fourteenth magnitude, M37 (NGC 2099), which contains about 150 stars between magnitudes 9 and 12.5, and M38 (NGC 1912), which has more than 100 stars fainter than eighth magnitude.

Aurora

An aurora is an extended source of light of different forms and colors observable at high latitudes and sometimes at mid-latitudes. Their brightness may reach the intensity of the full moonlight. The auroral oval (one in each hemisphere) is the location where most of the auroras are observable. It is a belt surrounding each of Earth's magnetic poles with a maximum latitudinal extent at magnetic midnight. The polar cap auroras (inside the oval) and daytime auroras are usually weak and diffuse while in the oval, they are more intense and variable in time. In both cases, auroras are generated by particles of solar origin interacting with the atoms and molecules of the Earth's upper atmosphere through direct collisions and chemical processes. However, in the case of the auroral oval, the particles are accelerated by some complex magnetospheric processes leading to phenomena of brighter intensity, of various forms, both characters being highly time dependent. The auroras are usually observed between 80 and 300 km high depending on the characteristics of the precipitating particles (electron and proton energies) and atmospheric composition, leading to an auroral spectrum made of many lines from atomic and molecular neutral or ionized species. The occurrence and intensity of auroras follow the solar activity; for example the typical 11-year solar cycle is found in the observations. The aurora's characteristics represent the last stage in a series of processes starting in the solar atmosphere and taking into account the Earth's magnetosphere and atmospheric physics.

Brief historical background

When observing our environment, different phenomena are revealed. There are regular phenomena such as sunrise and sunset, movements of stars and planets. There are also irregularly occurring phenomena, either of astronomical or geophysical nature, such as rainbows, comets, halos and auroras. Before becoming predictable, their occurrence was associated with some important events. This is why these phenomena were recorded for divinatory purposes and also likely for curiosity.

In the first few centuries AD some auroras were recorded by the Chinese, Greek and Romans. However, people living in the high-latitude regions were more accustomed to their occurrence and they named them the Northern Lights.

The first modern observations of auroras started in the second half of the sixteenth century with Tycho Brahe from his observatory at Uraniborg. Sometime later the occurrence of auroras decreased, especially at mid-latitudes. P Gassendi described several auroras, observed in the early seventeenth century, and suggested the name 'aurora borealis'.

After the discovery of SUNSPOTS in 1609, the Sun was regularly observed. Sunspot occurrence experienced a significant decrease from 1645 to 1715, the 'Maunder minimum', during which few auroras occurred. Solar activity resumed in the early eighteenth century and some intense auroras were observed at mid-latitudes (1716 and 1726). E Halley and later J J Dortou de Mairan were asked to study their origin by the Royal Society (London) and the Académie Royale des Sciences (Paris) respectively.

Various hypotheses had previously been made to explain the occurrence of auroras. Mairan suggested in 1733 that the auroral light was generated by a solar fluid impinging upon the EARTH'S ATMOSPHERE. Even though approximate, this was the first hypothesis based on a relationship between the Sun and the Earth. In the second edition of his report, Mairan felt there was a link between sunspots and auroras as well as their variations in seasonal occurrence. The relationship between the occurrence of auroras and magnetic perturbations was experimentally demonstrated by P Hiorter in 1741 by observing the tiny perturbations experienced by a compass needle (provided by A Celsius) at the same time. Mairan suspected that auroras could occurr in the southern hemisphere and addressed a note to Don Ulloa, a Spanish naval officer, who confirmed observations of a polar light when rounding Cape Horn in 1745. J Cook exploring the high southern latitudes confirmed the occurrence of the 'aurora australis' in 1770. In the second half of the eighteenth century, W Wargentin (1717–83) concluded from various observations that auroras are observable from different places at the same time and extend horizontally as a belt surrounding the North Pole.

After the discovery of the electron, K Birkeland proposed in 1896 that auroras were produced by electrons ejected from the Sun and guided by the Earth's magnetic field to the high-latitude regions. He supported this idea by laboratory experiments. However, due to electrostatic repulsion, it was necessary to consider a PLASMA ejected by the Sun rather than electrons alone. S Chapman and V Ferraro showed that a moving plasma will interact with the Earth's magnetic field, confining it in a cavity. This was the birth of magnetospheric physics.

Several expeditions at the end of the nineteenth century localized the auroral zone with accuracy. Auroras were the subject of many observations (forms, spectrum, etc) and theoretical developments.

Main properties

The modern means of auroral observations are spectrometers which analyse their spectrum, photometers which study the behavior of one or several emissions lines, cameras which record the aurora forms as a function of time, and radar. These instruments can be used on the ground or from orbiting platforms where they provide a global survey of auroras. However, before the instrumental study of auroras, observations were made visually. In order to allow comparisons of observations made by different authors, a nomenclature to describe auroral characteristics (intensity, form and color) was adopted internationally. It is still in use.

Intensity

The line of the greatest intensity is due to the emission of atomic oxygen at 557.7 nm frequently referred to in the scientific literature as the 'green line'. Auroral brightness is scaled to the green line intensity through the International Brightness Coefficient (IBC) as shown in table 1.

Table 1. The unit used is the rayleigh (R) which corresponds to 10^6 photons emitted in 4π steradians and received per cm^2 and per second. This scale was proposed by Seaton in 1954 and formalized by Hunten in 1955.

IBC	Intensity (kR)	Equivalent source
I	1	Milky Way
II	10	Thin moonlit cirrus clouds
III	100	Moonlit cumulus clouds
IV	1000	Full moonlight

For the purpose of comparison, equivalent brightness sources are indicated. For the modern measurements, auroral emission intensities are given in rayleigh. However, when using old records for long-term studies, the reference to the equivalent source intensity is useful despite its relative inaccuracy.

Forms and colors

Visual observations and images recorded by cameras reveal several typical forms as shown for example in figure 1. They are accurately described as arcs, bands, rayed or not, diffuse or pulsating surface, corona and flaming. The description of auroral forms is based on an international nomenclature shown in table 2.

Auroral colors are usually green, red or blue depending on the atmospheric species involved in the excitation processes. Auroras of intensity IBC I or II appear colorless. Yellow auroras are due to the blending of red and green auroras.

Auroral intensity is a function of time. The change may be either slow, as for a pulsating surface (0.1 Hz), or reach 10 Hz for certain homogeneous forms. Changes in time may be due to traveling forms as for the flaming-type auroras which appear to move upwards. Apparent horizontal movements are found in arc or band auroras with velocities as great as 100 km s^{-1}. This apparent velocity generally increases with the amplitude of the magnetic storm. When making visual observations of such events, the rapidity of the changes with time is certainly the most striking and spectacular feature of the auroral phenomenon.

Auroral events are due to precipitations of particles in the Earth's upper atmosphere. Their patterns are complex and this is why the description of an aurora needs to be accurately defined. Based on that, it has been possible to classify the auroral events and to obtain information about their generation processes.

Location

When observations are made on the ground as a function of latitude, a mean frequency of occurrence can be determined. It allows definition of the region of maximum occurrence now known as the 'auroral zone'. The auroral zone and auroral oval are two different concepts which will be explained later. Pictures of the auroral oval were obtained from orbit by the DYNAMICS EXPLORER 1 spacecraft (figure 2). The auroral oval center is shifted by about 3° from the geomagnetic pole towards the dark hemisphere. Its thickness is a maximum at magnetic midnight. The auroral oval lies around 70° magnetic latitude and has a mean width of about 5° in quiet conditions. When auroras are observed at the same time from two magnetically conjugate locations (one in the northern and the other in the southern auroral ovals), they develop similar patterns.

The occurrence of auroras is greater in the auroral oval than in its central part. This latter region is named the POLAR CAP and auroras have a weaker intensity and a smaller rate of change with time than in the auroral oval. Sometimes extraordinary auroral displays may be seen inside. For example, an arc observed near the zenith remains co-aligned with the Sun's direction. This was discovered by D Mawson in 1913 at the Dumont d'Urville station (Antarctica). This arc may extend up to both inner edges of the auroral oval. It was named the theta aurora as it looks like the Greek letter Θ.

The above auroras are observed at night. Another type of aurora is observable in the daytime. They are usually weak and diffuse.

Height and spatial extent

Heights were first measured using parallactic methods from the ground. Today, measurements from rockets and spacecraft are commonly used. Most auroral occurrence takes place in the altitude range 80 to 120 km. However, the lower border of very intense auroras may decrease to 70 km. Their vertical extent depends on the generation processes and may reach an altitude of 300 km for certain aurora. The intensity distribution is not homogeneous along the vertical; its vertical structure is made of elements having a thickness of hundreds of meters to some kilometers.

Auroras remain in a latitude strip, the thickness of which is function of the magnetic time (defined as the solar local time, but counted from the meridian containing the magnetic and geographic poles) as seen in figure 2. Within the auroral oval, the quiet arcs are mostly oriented in longitude along the oval and may be 500 km long.

Occurrence periodicity

For a given ground-based station within the auroral zone, the yearly mean occurrence follows the 11-year SOLAR CYCLE, with, however, a time lag of one to two years.

When using several years of data sorted by monthly mean, a semi-annual variation is shown with maximum auroral occurrence near the equinoxes. Similarly, the 27 day solar rotation can be pointed out. The occurrence

Figure 1. Auroral display observed at Dumont d'Urville (Antarctica). An all-sky camera of the Cassegrain type is also shown.

Table 2. Common auroral forms from Vallance-Jones (1974).

Homogeneous arc (HA)	Regular form in height, direction and intensity
Homogeneous band (HB)	Similar to HA, but variable along length
Rays arc or band (RA or RB)	Narrow with luminosity quasi vertically structured
Diffuse surface (DS)	Uniform emitting area
Pulsating surface (PS)	As DS, with intensity variable in time (several seconds)
Pulsating arc (PA)	As PS for an arc
Corona (C)	Ray system viewed parallel to the magnetic field lines
Flaming (F)	Forms of variable intensity moving towards zenith

of polar cap and daytime auroras does not strictly follow these rules, especially for the most intense events.

Relationship with magnetic activity

The Sun is a variable star. It experiences changes more or less cyclically, with some others of a more chaotic nature. Its variable activity induces fluctuations in the SOLAR WIND characteristics (velocity, density, ion and electron temperatures and magnetic field) of greater or lesser importance. It results in small fluctuations in the Earth's magnetic field which are detected by magnetometers on the ground. Their amplitudes are used to define indices of magnetic activity. These events are called magnetic storms. Auroral occurrence and intensity have been studied as a function of magnetic disturbance and the corresponding auroral oval has been determined. From a typical shape (figure 2), with increasing magnetic activity, the oval shifts slightly equatorward and extends polarward and equatorward. This explains why some auroras may be observable at mid-latitudes.

Magnetic activity follows the 11-year solar cycle pattern. However, given the chaotic nature of the Sun, strong magnetic events may occur even during low solar activity.

Electron and proton auroras

Auroras result mainly from collisions between atmospheric species and particles, electrons or protons. Most of the properties discussed above are those of electron auroras.

Differences between electron and proton auroras arise from their different mode of propagation in the upper atmosphere. Due to the proton mass, its radius of gyration is much greater (200 m) than the electron one. Furthermore, protons moving around the magnetic field may collide with some species and capture an electron. This results in an atom of hydrogen which moves in a straight line, free from the influence of the Earth's magnetic field. Another collision may later restore the initial proton. Consequently, proton auroras are of weak intensity (maximum IBC I) and diffuse. The height of occurrence is around 100 km. The proton auroral oval is shifted slightly equatorward with respect to the electron auroral oval.

The auroral spectrum and emission mechanisms

Most of the auroral displays are green due to the $O(^1S)$ emission line at 557.7 nm. However, many other lines from either atoms or molecular or ionized species exist. Figure 3 shows a spectrum between 450 and 750 nm. It

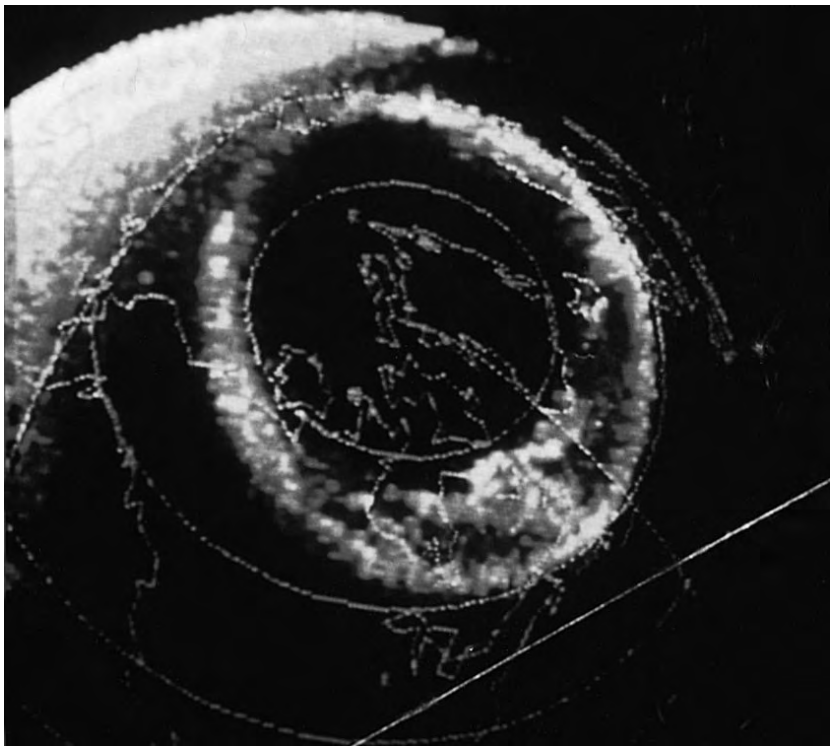

Figure 2. The auroral oval observed by the Dynamics Explorer 1 satellite (Frank *et al* 1982).

is a superposition of many lines from: O and N; O_2, N_2, NO and OH; O^+, N^+; and O_2^+, N_2^+. The blue color originates from the N_2^+ band at 391.4 nm. Figure 3 also shows the Balmer lines emitted during the proton events. The auroral spectrum arises from collisions between electrons/protons with the species in the Earth's atmosphere, and photochemical reactions:

(a) Collisions with electrons. Primary electrons from the magnetosphere are impinging upon the atoms (A) and molecules (M) of the terrestrial atmosphere and set these species in metastable states (*), such as

$$A + e \rightarrow A^* + e$$
$$M + e \rightarrow M^* + e$$

with similar reactions leading to ions. The electrons on the left-hand side are the primary electrons and those on the right-hand side are the secondary electrons which are also able to collide with other species and to generate excited molecular and atomic states until they are fully thermalized. The excited states (*) are deactivated either by radiating photons or by collisions with other species before light emission (quenching). As the density of the neutral species is increasing downward, quenching explains why no auroras are observed at low altitude (typically below 70 km).

(b) Indirect excitation mechanisms. The two most important mechanisms are:

(1) Dissociative recombination; a typical example is

$$O_2^+ + e \rightarrow O(^1D \text{ or } ^1S) + O.$$

(2) Energy transfer and quenching; a typical example is

$$O(^1D) + N_2 \rightarrow O(^3P) + N_2\dagger.$$

The symbol † denotes either an excited state or the ground state. For the first case there is an energy transfer, and for the second case there is a collisional deactivation. The efficiency of the quenching is a function of altitude and the lifetime of the excited state of the colliding species.

(c) Collisions with protons. Reactions involve protons and neutral hydrogen colliding with molecules. During these collisions, neutral hydrogen may lose its electron, ionize the molecule or transfer its energy to it. As for the proton, it may also ionize the molecule, transfer its energy or capture an electron.

To calculate the various emission line intensities, it is necessary to dispose of the energy spectrum of the primary electrons. This is generally measured at high altitudes (typically 300 km). The calculation of the auroral spectrum is based on the energy spectrum of the primary electrons, the cross section of the atoms and molecules,

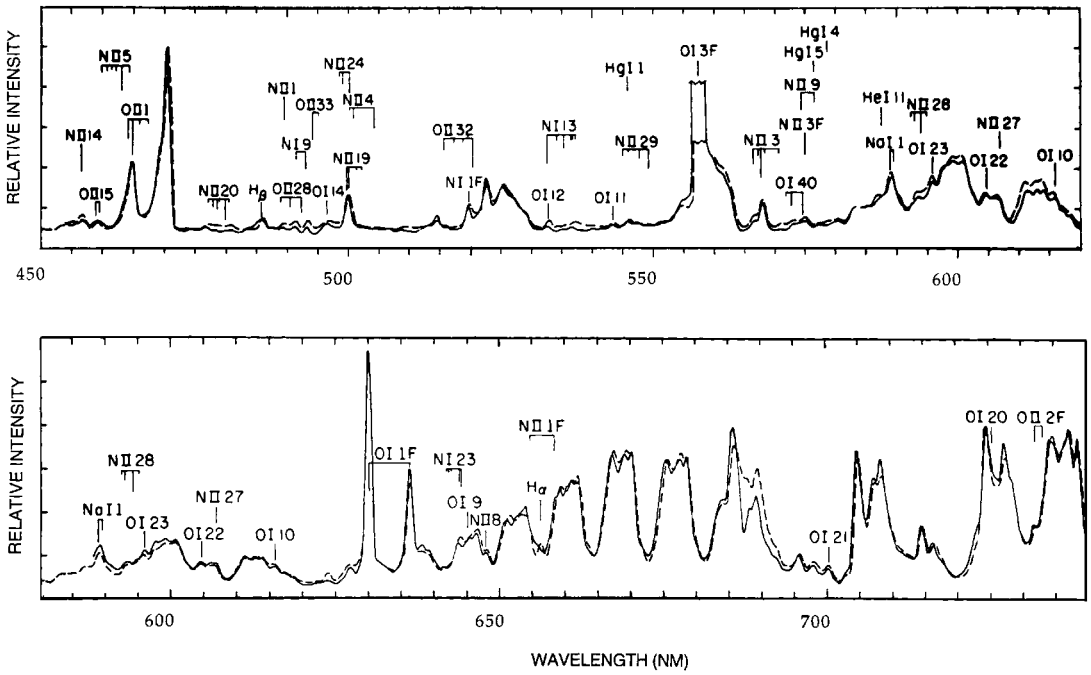

Figure 3. An auroral spectrum from 450 to 740 nm at 1 nm resolution. The observations (solid curve) are compared with the synthetic spectrum of Gattinger and Vallance Jones (1974). The green line intensity is in the range of an IBC II to III.

and the processes occurring as the electrons penetrate the atmosphere in a cascade of successive collisions. The problem is rather difficult and also suffers from the uncertainties affecting the cross sections.

Visual observations, as well as instruments on board rockets and spacecraft, have shown the dependence of the line emission intensity on altitude. Let us consider the case of the atomic oxygen emission at 630 nm. The mechanism of emission (dissociative recombination and excitation by collision), the vertical distribution of the neutral species and the energy spectrum of the precipitating electrons allow us to calculate the production rate of the excited state (^{1}D) as a function of altitude. Taking into account the deactivation of the excited oxygen atoms by collisions provides the emission rate profile with altitude. In the case of this emission, the 110 s lifetime of the ^{1}D excited state suppresses all emission at low altitude. This is why the aurora observed at 630 nm will be found around an altitude of 250 km. The same process allows us to calculate the altitude profile of the green line atomic oxygen ^{1}S excited state. Its lifetime, being 0.7 s, avoids the low-altitude deactivation and this emission will observable as low as 80 km depending on the intensity of electron precipitation.

For a given emission line, the stronger the electron precipitation is, the lower the aurora will be.

Aurora and the Earth's magnetosphere and other related phenomena

It is suggested that the reader consults the sections dedicated to the Earth's magnetosphere in order to have in mind its representation as well as the terminology (see MAGNETOSPHERE OF EARTH articles).

As the Sun is a variable star, the solar wind presents different regimes which affect the state of the Earth's magnetosphere. The interplanetary magnetic field (IMF) experiences changes with time. In the quiet condition, the IMF has a northward component (i.e. parallel to the terrestrial magnetic field) which turns southward during magnetic storms.

To investigate the mechanism of auroral emission, the spectrum of the precipitating particles has been measured during auroral display. For daytime and polar cap auroras, it was found to be of the order of the energy of the solar wind. Consequently, daytime auroras are believed to be generated by solar wind particles entering the upper atmosphere via the northern and southern dayside cusps where a neutral point exists in magnetically quiet conditions (northward IMF). Polar cap auroras are generated by solar wind particles from the magnetotail.

Within the auroral oval, particle energy is of a factor of 50 or more greater than in the solar wind. Consequently, the fundamental question is the acceleration mechanism of the particles. This is still being debated and cannot yet be considered as fully understood. However, reconnection between the Earth's magnetic field and the IMF is the most probable mechanism. A reconnection occurs when the IMF has a southward component (antiparallel to the terrestrial magnetic field). In this case, it generates a neutral sheath where the plasma jets are injected upstream and downstream from that region. It results in a thinning

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the plasma sheet and an inward movement of the particles. The shrinking of the plasma sheet leads to an increase in the energy of the particles. Several processes are proposed. The most likely is based on adiabatic compression of a certain quantity of plasma being confined in a compressed magnetic flux tube as it is convected forward until it is finally precipitated into the Earth's upper atmosphere just as the system becomes unstable.

The auroral oval is then the intersection of the plasma sheet with the upper atmosphere in the 100–200 km altitude range. The auroral oval is fixed with respect to the Sun, but a ground-based station at auroral latitudes rotates below, around the geographic pole. As a function of time, it may be in the polar cap, inside or outside the oval, experiencing different auroral occurrence regimes. Their mean defines the auroral zone as seen from the ground.

When the magnetosphere is moderately disturbed due to small IMF changes, the corresponding events are called magnetic substorms, which are made up of four distinct phases (quiet, growth, expansion and recovery) having specific characteristics such as typical changes in the Earth's magnetic field. Major solar events such as FLARES generate magnetic storms which are analysed as a series of successive substorms.

During a magnetic storm, the moving particles generate a magnetic field which combines with that of the Earth. The variable characteristics of the precipitating particles (velocity, direction and number density) and the collisions with the Earth's atmospheric species are the cause of the complexity of the magnetic field disturbance. Consequently, auroras constitute a visual illustration of the perturbations of the Earth's magnetic field. In certain cases, the field pattern is simple, as for example the rays which appear as nearly vertical columns of light showing the high inclination of the field line at the latitude of the auroral zone.

Associated with auroras are many other phenomena such as the auroral electrojet circulating in the E-region (around 100 km altitude) which is heated by Joule dissipation and a ring current at low latitudes. Also, x-rays and radio waves are generated in the range of 40 to 500 MHz. During auroras, electric fields are created, acting on the movement of the electrons, protons and ions. Furthermore, all these species are moving in a neutral atmosphere which is driven by collisions with the ions. Consequently, dynamics are strongly involved in the auroral events as illustrated by the development of vertical neutral winds during the substorms.

The use of auroral observations

The link between auroral occurrence and solar activity has been statistically established from observations. This is why the occurrence of auroras has been used to reconstruct the solar activity before the first instrumental observations. The long periods in the solar activity found in the ^{14}C variations were confirmed by the occurrence of auroras. More directly, auroral occurrence represents the ultimate stage in the various phenomena taking place from the solar wind up to the Earth's atmosphere. Understanding the detailed auroral characteristics (occurrence, forms, spectrum) ensures that the entire physical process is understood. The same applies to auroras observed in the atmosphere of Jupiter and Saturn.

Auroral data show how important in science are a long series of carefully made observations.

Aurorae: Observing by Amateurs

Amateur scientists have had a long interest in the sky, so there has been an amateur involvement with observing the aurora for as far back as records exist. In the modern era, amateurs have been credited with making significant contributions to investigations of the aurora since advancements in many sciences began to escalate during the 18th century. Because the aurora is a large-scale, global phenomenon, the value of international collaborations involving both professionals and amateurs was recognized early. One of the most successful demonstrations of such cooperation occurred during the International Geophysical Year (1957/58).

With the advent of the space age, investigators have come to rely more on satellites and sophisticated ground-based observatory equipment to monitor the aurora, but some value is still placed on visual reports to supplement these. An important purpose of the visual observation is in continuing the written records of auroral activity that have been preserved by several civilizations since Greek times.

A minimum of equipment is required to make useful visual observations of the aurora, and the only optical instrument needed is the unaided eye. To a certain extent, it is possible to forecast the occurrence of auroral displays based on recent events on the Sun, so that observing efforts can be planned to coincide with the nights when a display is likeliest to occur. Magnetometers and short-wave radios can also be helpful in alerting the observer to the presence of auroral activity (although there is not always a visual counterpart). You will see auroral displays most often, however, if you persevere with making regular visual inspections of the poleward sky throughout the night, between sunset and dawn, whenever weather and moonlight permit.

Amateur observers living in cities or where there is frequent cloud cover may not be able to observe the aurora visually very often, but they can nonetheless submit an observation that auroral activity was detected by a magnetometer or short-wave radio. In this case, the observation is not confined to the night-time hours as for the purely visual observer.

No special equipment is needed for basic aurual observations. It can be useful, however, to have an instrument, such as a simple theodolite or alidade, to accurately determine the bearings and heights of features in the aurora. As an adjunct to the visual record, amateur observers sometimes detect subvisual details in auroral displays with photography or CHARGE-COUPLED DEVICE (CCD) imaging.

Photography is a popular way of recording an aurora and is the ideal means by which to share the spectacle of a display after the event (figures 1 and 2). All that is needed is any camera that can make time exposures of a few seconds to a few minutes, with the lens open to its widest aperture—many photographers choose fast color film (such as ISO 400), and a fast, wide-angle lens (such as $f/3$ focal ratio and 28 mm focal length). Photographs also make a permanent record of the position and structure of a display, which may be useful for triangulation work. For those interested in applying other techniques to expand on their observations, videography, CCD imaging and spectroscopy may also be employed.

As a means of identifying the presence of, or forecasting the likelihood of, auroral activity, observers with an interest in electronics may use magnetometers or short-wave radios to detect disturbances in the geomagnetic field or the ionosphere.

Contributors are encouraged to submit observations of aurorae in a format recommended by international agreement, which increases the value of a sighting and also the observer's appreciation of the phenomenon. A record includes the observer's location and observing

conditions, the date and time that a display was seen, plus details about brightness, color, form, activity, directions and elevations of features, and changes that occur. This information can be recorded as notes or diagrams, reported to varying degrees of detail according to the individual observer's preference or experience.

Any photographs or other types of observation of the aurora should also be accompanied by a record of at least location, date and time, plus relevant technical information, to give them scientific value. This also increases the interest and usefulness of the record to other observers.

To make the best use of observations, results can be contributed to one of several well-established organizations that collect, analyse and archive the reports for future use.

Initial analysis of reports usually includes a comparison with the forecasts and a correlation of the auroral event with activity on the Sun and in the Earth's geomagnetic field. For the longer term, it is interesting to determine the frequency of displays seen from particular locations and their frequency under certain conditions or at particular times of the year or the sunspot cycle.

An aurora reported by a number of observers from different locations allows that aurora's shape, size, position, development and duration to be described. Results shared between regional and international organizations make it possible to chart an entire auroral event, across the daylight boundaries and between hemispheres, so that the global pattern of auroral activity can be studied. The visual observations can ultimately be compared with images and other data about the auroral oval obtained from satellites and professional observatories.

The British Astronomical Association (BAA) collects observations of the aurora through its Aurora Section and has a network of observers who include members of the BAA or other astronomical societies, individual observers, professional meteorologists and ships' officers at sea. The BAA collects and publishes observations, mainly of the mid-latitude storm aurora, from the British Isles, Europe, Iceland, Canada and the United States of America; they are also published by the British Meteorological Office. In the southern hemisphere observations are coordinated by the Royal Astronomical Society of New Zealand (RASNZ), which receives and publishes observations from New Zealand and Australia. There is close cooperation and exchange between the BAA and the RASNZ.

Reports coordinated by the BAA and the RASNZ are then archived at Aberdeen University, Scotland, where they are available to researchers. There are similar archives in such countries as China, Korea and Japan.

Radio observations of the aurora are coordinated by the Radio Society of Great Britain and the American Radio Relay League in the USA.

Professionals draw on the data contributed by amateurs; for example, amateurs' results have helped to reveal processes in the thermosphere. Amateur observers are also important contributors to ongoing investigations into the complex correlation between the aurora and noctilucent clouds.

Auroral processes and the complex interactions that cause them are not yet fully understood, so the aurora is still under vigorous investigation. Since scientists no longer record the visual aurora, the only source of such observations is the amateur astronomical community. Records of the visual aurora have been kept for hundreds of years, and in the past they have provided valuable insights into solar activity and the Earth's upper atmosphere—there are extensive archives yet to be exploited that may be of similar importance in new studies in the future. Some of the areas that may make use of records of the visual aurora include geomagnetism, solar and interplanetary magnetism, terrestrial weather, the upper atmosphere and space weather.

Auroral Kilometric Radiation

The Earth is a powerful natural radio source that emits a bright emission at kilometric wavelengths: the auroral kilometric radiation (AKR). As indicated by its name, the source regions of the AKR are at high latitudes, at altitudes ranging from typically 0.5 to 2 Earth radii. Its maximum frequency (of the order of 700 kHz) is smaller than the ionospheric cut-off frequency and therefore this radiation cannot be observed from the ground. It was thus discovered and studied after the beginning of the space era (Benedictov *et al* 1965).

The AKR is organized in radio storms lasting a few 10 min and having power as strong as a few megawatt. This sporadic activity is correlated with periods of intense auroral particle precipitations during which energetic electrons with typical energies of a few keV are observed flowing down along the auroral magnetic field lines and forming the aurora borealis (see AURORA). These precipitating electron populations result from a complex chain of physical processes linked to the major disruptions of the magnetospheric tail known as magnetospheric substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS). The AKR is thus directly related to the global magnetospheric activity and can even be considered as an indicator of this activity. Concerning its intrinsic properties, the AKR is characterized by its extreme brightness temperature (up to 10^{20} K) which is completely unexplainable by classical radiating mechanisms (as gyrosynchrotron radiation). Coherent processes, related to the development of plasma microinstabilities, must then be invoked for explaining its generation. In addition to this extreme brightness, a good theory of the AKR must also describe the polarization of the emission and its strong temporal and spectral organization.

The AKR is not by itself a particularly powerful phenomenon. It is even neglectable in the global energy budget of magnetospheric activity. However, it presents some astrophysical interest since it belongs to the wide class of radio emissions directly related to the development of acceleration mechanisms in the collisionless plasmas that surround most astrophysical objects (see COLLISIONAL PROCESSES IN ASTROPHYSICAL PLASMAS). Radio emissions presenting characteristics comparable with the AKR have indeed been observed coming from astrophysical objects as different as the other magnetized planets of the solar system, the Sun, some stars and binary systems (see MAGNETOSPHERES: JUPITER, RADIO EMISSIONS, RADIO EMISSION FROM BINARY STARS). As its sources can be directly explored by spacecraft, the AKR thus constitutes a very interesting case of an astrophysical phenomenon for which theoretical models can be checked using *in situ* measurements. Most of the above-mentioned radio emissions probably originate from the very site of particle acceleration and their analysis can serve as a diagnostic tool for the study of the energy release in plasma environments. In this context, the understanding of the generation mechanism of the AKR is crucial. The observations reported below concern this particularly important aspect of the problem.

Physical conditions within the sources of AKR

An example of the precise wave observations performed near and inside the source of the AKR is given in figure 1. These measurements have been obtained by a Swedish spacecraft—Viking—specially designed for the analysis of the acceleration and radiating mechanisms taking place in the auroral zones of the MAGNETOSPHERE OF EARTH. When it made this observation, Viking was at an altitude of the order of 10 000 km, at a magnetic latitude close to 70° North, around midnight local time, and crossed a region magnetically connected to a discrete auroral arc. In the figure, a time–frequency diagram of the electric component of the electromagnetic waves is presented. The intensity is given by a color code (from blue to red and white as the intensity increases from less than 10^{-8} V m^{-1} Hz$^{-1/2}$ to more than 10^{-5} V m^{-1} Hz$^{-1/2}$). The frequency range is 10 kHz–500 kHz and 20 min of data are shown. A white line indicates the electron gyrofrequency (f_{ce}) measured by the spacecraft. The AKR is observed above this characteristic frequency (here around 150 kHz), forming V-shaped emissions. Its lower frequencies which correspond to a clear cut-off has a minimum around 22.39 UT. At that time, the AKR frequencies extend down to f_{ce}. This region of minimum frequencies is also the region of maximum level of the waves (white intensity code). This is the source of the AKR. The V shape of the AKR dynamic spectra is easily understood if one assumes that the waves are generated at f_{ce} (thus at increasing frequencies as the altitude decreases) in a source elongated along the magnetic field, at oblique angles from the magnetic field lines and in the upward direction. Far from the source (for example at 22.35 or 22.45), only waves generated well below the spacecraft (thus at high frequencies) are detected. As the spacecraft approaches the source, waves generated closer and closer to the spacecraft and thus with lower and lower frequencies are detected, until the spacecraft crosses the source which corresponds to a maximum intensity and minimum frequencies. On this spectrogram, one can also observe a systematic modulation of the AKR, in the whole frequency range, at a period of 20 s. This modulation is linked to the spin of the spacecraft (the electric antenna are then alternately parallel and perpendicular to the magnetic field) and is an indication of the strong polarization of the waves. This can be used to identify the mode of propagation of the AKR. One finds that it is the so-called X mode, an electromagnetic supraluminous mode that has a right-handed circular polarization (the electric component of the waves rotates in a plane perpendicular to the magnetic field in the same sense that the electrons).

In the lowermost part of the spectogram, a broadband emission (the auroral hiss) is observed. The upper-frequency cut-off of this emission (yellow to green transition on the spectrogram) is the local plasma frequency. It is of the order of 30 kHz indicating that the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

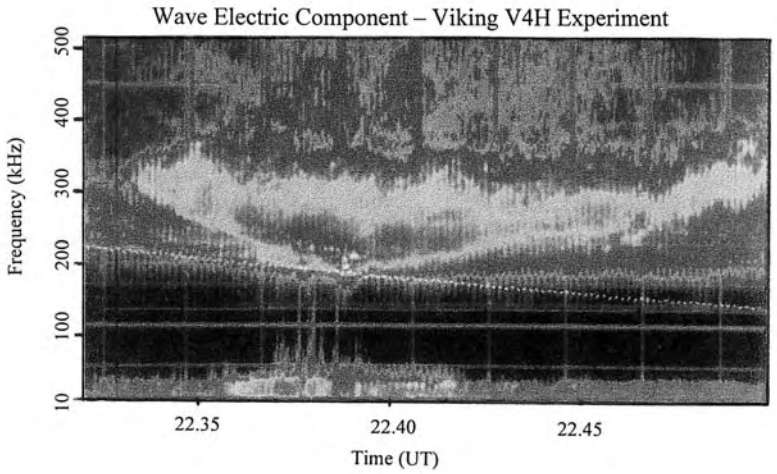

Figure 1. This figure is reproduced as Color Plate ??.

plasma density is typically about 10 cm^{-3}. Just around 22.39, during the crossing of the AKR source, this cut-off disappears. It is in fact below the frequency bandwidth of the analyser (10 kHz). The source of AKR is then a region of significant plasma depletion, the typical density varying from typically 10 cm^{-3} to less than 2 cm^{-3} over a short distance (a few km). The sources can then be seen as 'curtains' of depleted plasma, with rather large vertical and East–West extensions but very thin (less than 50 km) in the North–South direction.

Particle measurements are important for an understanding of the generation mechanism. In figure 2, time–energy spectrograms for the electrons (upper panel) and the ions (lower panel) are presented. The energy goes from 40 eV to 40 keV and the intensity of the flux is given by a color code. Because of the spin of the spacecraft, the particle fluxes are measured at variable angles with respect to the magnetic field (sawtooth below the proton fluxes). 0° corresponds to the direction parallel to the magnetic field, oriented towards the Earth (precipitating particles). For the data presented in figure 2, we know from wave measurements (not shown here) that a source of AKR has been crossed between the two arrows. This time interval corresponds to the detection of ion beams that propagate upward with typical energies of the order of 4 keV. Simultaneously, the maximum energy of the electrons decreases from 8–10 keV (before the first arrow and after the second one) to typically 4 keV (between arrows). The most simple explanation of these observations is that, when entering the AKR source, the spacecraft also enters a region of particle accelerations that corresponds to the existence of a potential drop along the magnetic field. Just before or after the source crossing, this potential drop is entirely above the spacecraft so that precipitating electrons of maximum energy are detected. Inside the source, a part of the potential drop is now below the spacecraft; the energy of

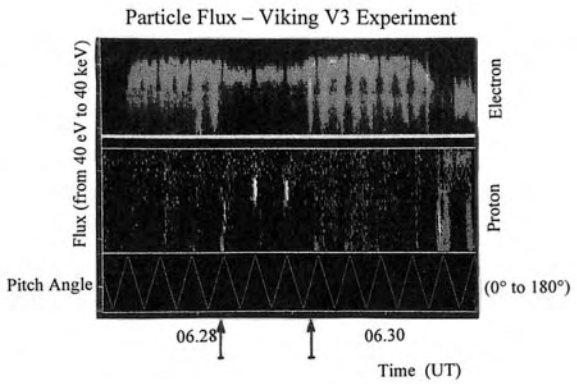

Figure 2.

the electrons decreases but energized ions coming from below are observed. This constitutes one of the fundamental observations concerning the AKR: the sources of this radiation are also the sites of the particle acceleration (Louarn *et al* 1990). This was recently confirmed by observations of the FAST spacecraft (Ergun *et al* 1998).

A more precise study of the fluxes of particles can help us to understand the type of distribution functions that are responsible for the wave generation. These distributions are characterized by expanded loss cones (large gap in the flux of upward electrons) and an accumulation of electrons at rather large perpendicular and small parallel velocities. The formation of such distributions can be explained by the creation of the parallel electric field responsible for the particle acceleration. This also corresponds to the evacuation of the low-energy plasma and to the formation of the region of density depletion. These two characteristics of the distribution functions, accumulation

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of electrons at high perpendicular velocities and low densities, are of fundamental importance for the most plausible generation mechanism of the AKR: the cyclotron maser instability.

The cyclotron maser theory

Many theories have been proposed in the past to explain the generation of the AKR (linear mode conversion of electrostatic upper hybrid waves, non-linear beating of electrostatic waves, radiation from collapsing cavitons). It is now widely accepted that a particular microscopic instability—the cyclotron maser instability (CMI; first proposed by Wu and Lee (1979))—adequately describes the phenomenon. This theory is based on a resonant interaction between the electric field of the waves and the gyrating electrons and describes a transfer of angular momentum from the electron population to the wave electromagnetic field. The success of this theory is explained by the fact that it takes into account some of the most important experimental results presented before. The angular momentum transfer is particularly important if the electric field follows the electron motion, i.e. if the waves present a right-handed circular polarization (which is the case of the X-mode waves). Moreover, this transfer is to the advantage of the waves if the plasma presents an excess of angular momentum with respect to the thermal equilibrium. Such an excess can correspond to the existence of positive $\partial f/\partial P_\perp$ slopes in some region of the momentum phase space (where $P_\perp$ is the component of the particle momentum perpendicular to the magnetic field) which is precisely what is observed inside the source regions of the AKR. This mechanism of generation is then just a particular example of wave excitation by an out-of-equilibrium plasma characterized by an inversion of population in 'perpendicular' energy.

This mechanism can be described in a more mathematical way using the Maxwell–Vlassov system of equations. If one retains only the most important interaction between the waves and the electrons (pure cyclotronic motion and interaction with a homogeneous electric field that rotates in the right sense at a frequency close to the electron gyrofrequency), the system can be written as

$$\frac{\partial \boldsymbol{E}_1}{\partial t} = -\frac{\boldsymbol{J}_1}{\varepsilon_0}$$

$$\left(\frac{\partial}{\partial t} + \frac{\omega_c}{\Gamma}\frac{\partial}{\partial \theta}\right) f_1 = \frac{e}{\sqrt{2}}(E_{1+}\,e^{-i\theta} + E_{1-}\,e^{+i\theta})\frac{\partial f_0}{\partial P_\perp} + eE_\parallel \frac{\partial f_0}{\partial P_\parallel}. \quad (1)$$

Here f_0 is the background distribution function, E_1, J_1, f_1 are the perturbed electric field, current and distribution function, respectively, the subscripts $+$, $-$ and $\parallel$ refer to left-, right-handed and parallel components, θ is the Larmor angle of the electrons, Γ their Lorentz factor $((1-v^2/c^2)^{-1/2})$ and ω_c the electronic gyrofrequency. From a temporal Fourier transform of equation (1), a simplified dispersion equation is obtained:

$$\omega = \pi\omega_P^2 \iint \frac{dP_\parallel P_\perp^2 dP_\perp}{\Gamma} \frac{1}{\omega - \omega_c/\Gamma}\frac{\partial f_0}{\partial P_\perp}. \quad (2)$$

The growth rate of the waves is then easily calculated. It is proportional to to integral of $\partial f_0/\partial P_\perp$ along the resonant curve defined by $\Gamma\omega = \omega_c$. This means that the maximum transfer of momentum occurs if the wave frequency exactly matches the gyrofrequency of the electrons. A slightly more complex calculation gives the exact resonant condition: $\omega - k_\parallel v_\parallel - \omega_c/\Gamma = 0$. For $\partial f_0/\partial P_\perp > 0$ along the resonant curve, the absorption coefficients can become negative, thus leading to an instability: the so-called CMI. The exact and complete calculation makes the dispersion equation more complex but does not change its physical meaning.

Two physical processes could be responsible for the formation of $\partial f_0/\partial P_\perp$ non-thermal features in the distribution function: (1) the ionospheric absorption of the electrons which produces loss cone distributions functions and (2) the adiabatic evolution of electron populations accelerated downward along the magnetic field lines. Because of the mirror force, their perpendicular energy indeed gradually increases at the expense of their parallel energy such that a local excess in perpendicular momentum can be formed. The presence of an accelerating electric field also favors the occurrence of the maser instability in another way: it evacuates the cold electrons, a plasma component that always contributes to stabilize the CMI. For the X modes to be unstable, it is indeed necessary that, roughly speaking, $(\omega_{pc}/\omega_c)^2 = W/2mc^2$, where ω_{pc} is the cold plasma frequency and W the typical energy of the electrons—with rest mass m—for which $\partial f_0/\partial P_\perp$ (Melrose 1986).

Although *in situ* observations provide strong evidence that the AKR is generated by the CMI, the growth rates directly determined with the measured distribution functions are not necessarily very meaningful. This is because of the sensitivity of the instability to the various inhomogeneities existing in the plasma and/or its fast saturation by non-linear processes. Among the various gradients present in the magnetospheric medium, two of them probably affect the AKR generation: (1) the inhomogeneity of the magnetic field that induces slight modifications of the gyrofrequency with the altitude such that the resonant condition cannot be fulfilled over a very large distance and (2) the perpendicular inhomogeneity linked to the existence of the sharp density gradients that limit the AKR sources (Le Quéau *et al* 1985, Louarn and Le Quéau, 1996). These effects could have some importance in the determination of the macroscopic properties of the radiation (shape of the emitting lobes, in particular). Concerning the non-linear effects, the growth of the waves can saturate either by quasilinear relaxation or by a trapping-type saturation process, which is still a matter of debate. The non-linear saturation and the inhomogeneity effects could be important for explaining the formation of some of the fine structures observed in the AKR dynamic spectra.

Conclusion

The AKR can be considered as a relatively well-understood magnetospheric phenomena. The sources of this radiation

have been explored and a theory—the CMI—gives a good qualitative explanation of its generation. However, there is no complete theory that can explain some quantitative aspects of the radiations. For example, starting with a given unstable distribution function, the prediction of the final intensity of the waves and of their spectral characteristics is still an open question. This is an important issue since it is only with solutions to this type of problem that radio waves could be used as precise diagnostic tools.

Australia Telescope National Facility

The Australia Telescope National Facility (ATNF), created in 1989, operates the Australia Telescope Compact Array, the only radiosynthesis array in the southern hemisphere. The array, opened in 1988, consists of six 22 m diameter antennas, which together simulate a single antenna 6 km in diameter. It is located near the town of Narrabri, about 580 km northwest of Sydney. The array has high resolving power, wide bandwidth, good spectral-line capability and the ability to accurately measure polarization to low levels. New techniques employed with the instrument include the 'mosaicing' of large fields and 'pulsar gating'. It has been used to make the first three-dimensional image of Jupiter's magnetic field, and has followed the radio evolution of the remnant of Supernova 1987A, the most important supernova of modern times.

The ATNF also operates the 64 m diameter Parkes radio telescope (opened in 1961). The premier instrument is a cooled 21 cm multibeam receiver which is located at the prime focus of the telescope. This instrument was installed in 1997, and allows deep observations to be made of large areas of sky. The feed cluster is an arrangement of 13 beams placed on a hexagonal grid. This receiver has been used recently to find hundreds of new galaxies, previously hidden by obscuration by galactic dust, and to find hundreds of new pulsars in the Milky Way. It is also being used to conduct the H I Parkes All-Sky Survey (HIPASS), the first wide-angle 'blind' survey aimed at surveying the nearby universe in the 21 cm transition of neutral hydrogen.

The ATNF's third telescope is a 22 m diameter antenna used for millimeter-wave observing. It is located near the town of Coonabarabran, half-way between the other two observatories.

Antennas from all three observatories are used together and with those of other institutions for very long baseline interferometry experiments.

Part of CSIRO, Australia's largest national research organization, the ATNF has 135 staff and an annual operating budget of A$13 million, most of which is direct funding from CSIRO.

The objectives of the ATNF are to: operate and develop the Australia Telescope as a national research facility for use by Australian and international researchers; to exploit the telescope's unique southern location and technological advantages to maintain its position as a world-class radioastronomy observatory; and to further the advancement of knowledge.

Australian Astronomy

Astronomy has been one of the principal sciences in Australia since the first European settlement over 200 yr ago. In the modern era, the access to the rich southern skies and a tradition of innovation in instrumentation sustain an active and diverse research program.

Early history

The main objective of Captain James Cook's voyage in 1769, during which he discovered and charted the east coast of Australia, was to observe the transit of Venus from the South Seas. The exact time at which Venus transited the disk of the Sun provided a more accurate value of the distance from the Earth to the Sun, and indeed the size of the entire solar system, as first suggested by Kepler. When the first European settlement was made at Sydney Cove in 1788, the importance of navigation, surveying and time-keeping was the reason for setting up an observatory. Later, official State observatories were founded, the first being Sydney Observatory in 1855. It provided a time service for ships in Sydney Harbor and contributed to the astronomical research of the day, particularly stellar positional astronomy. It finally produced 53 volumes of the Cart du Ciel (International Astrographic Catalogue) project.

State observatories were also set up in Perth and Melbourne—the latter becoming well known because of its acquisition of the Great Melbourne Telescope. This was a 48 in (1.2 m) telescope and at its erection in 1869 was the largest fully steerable telescope in the world. Some of its early photographs of the Moon were hailed as the best to date, and visual observations of southern nebulae were made which greatly improved on those made by Sir John Herschel in his pioneering work from the Cape of Good Hope (see HERSCHEL FAMILY). Nevertheless, problems with the speculum mirror and wind-shake due to the use of a roll-off building, among other things, led to the telescope falling into disuse by the end of the century. The problems with the Great Melbourne Telescope set back the building of large telescopes by many years, and the next one was the Mount Wilson 60 in (1.5 m) built in California in 1908 and arguably the first of the modern telescopes. The Great Melbourne Telescope was sold to Mount Stromlo Observatory and in recent years (with new optics) has been used in the MACHO search for gravitational lensing by stars. Today, of the former colonial observatories, only Perth Observatory retains a research role.

Post-war development

The modern era of astronomy in Australia began immediately after World War II. The impact of wartime technical developments was most noticeable in the new field of RADIO ASTRONOMY, where the expertise in radar systems and the surplus equipment available formed an ideal base. In Australia the work was carried out at the Radiophysics Laboratory of the CSIR (Council for Scientific and Industrial Research, later CSIRO). At this time little was known about radio emission from outside the Earth: Karl Jansky had discovered radio waves from the Milky Way Galaxy in 1932 while working on sources of noise in radio transmissions, and another American, Grote Reber, had built a 31 ft dish antenna in his own backyard and made the first broad-scale maps of the Galactic emission. Finally, a wartime investigation of suspected radar jamming had been traced to unusually intense radio emission from the Sun.

It was in this climate that the radio astronomy groups in the United Kingdom, the Netherlands and Australia began their work. The radiophysics work was carried out at a number of field stations in the Sydney area, and discoveries came quickly: for example the correlation of solar emission with sunspot number and the demonstration of an effective temperature of about one million kelvins, far above the optical surface temperature of about 6000 K. Perhaps the best-known work was carried out with a cliff-top INTERFEROMETER, which was used to discover a number of isolated radio sources and to show that they had very small angular size. The identification of several of these sources with known optical objects, including the Crab Nebula and external galaxies in the constellations of Virgo and Centaurus, showed that radio astronomy would have much to teach us about distant objects. Development of interferometry continued, as a way to overcome the coarse angular resolution of early radio telescopes. The early 'radio star' theory of the nature of the discrete radio sources was shown to be incorrect because the majority of radio sources away from the plane of the Milky Way Galaxy had angular sizes greater than 1 arcmin. They became known as RADIO GALAXIES, in recognition of a radio power output thousands or even millions of times greater than that of a normal galaxy. Surveys of such sources showed an excess of faint sources, but less pronounced than in the early surveys carried out at Cambridge, which were shown to be affected by 'confusion' of multiple sources within the instrumental beamwidth. Later counts of these distant extragalactic sources, from both Cambridge and Sydney, were in agreement and played a pivotal role in cosmological controversies, in particular the demise of the STEADY-STATE THEORY.

Wartime developments also had an impact on OPTICAL ASTRONOMY, although this was already one of the oldest-established sciences overseas. The Commonwealth Solar Observatory at Mount Stromlo near Canberra had been established in 1924 and expanded during the war to manufacture gunsights and other optical munitions. After the war the research field was changed to stellar astronomy, and the name was changed to the Commonwealth Observatory and later to Mount Stromlo Observatory. Modernization of the instrumentation, for example the introduction of photoelectric techniques, proceeded in parallel with numerous research programs. The MAGELLANIC CLOUDS have long been much studied from Mount Stromlo: these near-neighbor galaxies have the great advantage of being at a known distance, yet

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

being close enough that star clusters and the brighter stars can be discerned individually. In 1955 the 74 in (1.88 m) telescope was commissioned at Mount Stromlo and, together with a similar telescope in Pretoria, was the largest optical instrument in the southern hemisphere for some 20 yr. Prompted by the growth of the nearby city of Canberra, a site at Siding Spring Mountain near the town of Coonabarabran in New South Wales was selected for future telescopes, and the name changed to MOUNT STROMLO AND SIDING SPRING OBSERVATORIES (MSSSO). The observatory has been part of the Australian National University for many years, and is now the Research School of Astronomy and Astrophysics.

The era of the CSIRO radiophysics fieldstations drew to a close in the early 1960s, with the decision that the increasing sophistication of radio astronomy required the resources to be concentrated into a much smaller number of major instruments. These were the 210 ft (64 m) fully steerable paraboloid at Parkes and the Culgoora Radioheliograph. The Parkes telescope was completed in 1961, when the only other large dish telescope was the Jodrell Bank (UK) 250 ft (76 m). A notable early result from the Parkes telescope was the lunar occultation observation which pinpointed the position of 3C 273, allowing identification with the star-like object which first revealed the great optical redshifts of quasars. The telescope was soon well known for its high-frequency radio surveys, which resulted in the discovery of many quasars, and also for its support during the 1960s and 1970s of the NASA Apollo missions to the Moon. Many other projects have occupied the telescope over the years, covering both spectral line and continuum, Galactic (including pulsars) and extragalactic sources, polarization studies etc.

The Culgoora Radioheliograph consisted of 96 simple dishes of 13 m diameter, arranged in a circle of diameter 3 km on a site near Narrabri, New South Wales. It was completed in 1967. In this era before the use of computers to create images from raw data, ingenious hardware was used to enable a two-dimensional image of the Sun to be synthesized every second. Separate images in the two polarizations revealed further information about plasma emission processes on and above the Sun's disk. The original operating frequency of 80 MHz was later augmented with capabilities at 43, 160 and 327 MHz. The radioheliograph was closed down in 1984, and the site used for the Australia Telescope Compact Array.

The 1960s also saw the construction of the 1 mile Molonglo Mills Cross radio telescope, a transit instrument designed for rapidly surveying the sky at 408 MHz. Operated by the University of Sydney, it enjoyed early success in finding many pulsars, soon after this class of object was discovered at Cambridge. The Molonglo Cross went on to produce a survey of the southern sky, as well as numerous studies of particular classes of object. In 1978 operation as a cross was halted, and the east–west arm was converted to aperture synthesis at 843 MHz, as the MOLONGLO OBSERVATORY SYNTHESIS TELESCOPE (MOST). In this form it has improved sensitivity and image-forming capability. The field of view has since been further enlarged to nearly 2°, and the telescope is carrying out the 'SUMSS' survey of the entire southern sky with a resolution and sensitivity similar to those of the NVSS northern (and equatorial) survey. Another radio telescope project of the 1960s was the Fleurs Synthesis Telescope, converted from an earlier CSIRO grating cross instrument to aperture synthesis operation by the University of Sydney. It provided the highest angular resolution radio imaging in the south for many years, but was superseded by the Australia Telescope and has since been closed down.

A novel instrument of the 1960s was the Narrabri Stellar Intensity Interferometer (NSII). The principle of intensity interferometry had been developed and tested in the context of radio astronomy, and had the advantage of being unaffected by observation through a turbulent medium. Applied to optical observations, this enabled the NSII to observe the angular diameters of stars down to 0.0004 seconds of arc. The instrument was operated by the University of Sydney and comprised two large (6.5 m) REFLECTORS on a circular rail track of diameter 188 m. It successfully observed the sizes of the 32 stars within its sensitivity limit, thereby defining a true temperature scale for hot stars. The instrument was then closed down and work commenced on the Sydney University Stellar Interferometer (SUSI), a 'modern Michelson' instrument using interference of two beams of light from widely separated siderostats instead of correlating the radiofrequency fluctuations as in the NSII. SUSI is located on the same site as the Australia Telescope Compact Array and when fully commissioned will have baselines up to 640 m, giving the highest angular resolution of any of the current optical interferometer projects. As well as extending stellar diameter and hence effective temperature measurements to a very much greater range of stars, a key program will be to observe directly the radial pulsation of Cepheid variables, thereby improving the use of these stars as distance indicators.

The National Facility instruments

It was clear by the 1960s that a larger general-purpose optical telescope was needed, both to extend the existing stellar and galactic work and to pursue the optical identification of radio sources. Astronomers in the UK also felt the need for a larger instrument, and an agreement was reached between the Australian and UK governments which resulted in the construction of the 150 in (3.9 m) Anglo-Australian Telescope (AAT) on the existing Siding Springs site. Completed in 1974, the AAT incorporated innovations in servo drive systems, mirror support and especially notably in computer control. The resulting pointing precision of a few arcseconds was unprecedented at the time and allowed any observer to readily locate even faint objects. The AAT is operated by the ANGLO-AUSTRALIAN OBSERVATORY (AAO), an organization which was set up for this purpose. An early success with the AAT was the detection of optical pulses from the Vela pulsar, at the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

time the faintest object ever recorded (24th magnitude). Although the Siding Spring site is not as good as the best in Hawaii or Chile, the AAT is a highly productive telescope, largely because of the strong technical support and continued investment in new instrumentation. In the current era of 8–10 m class telescopes, the AAT continues to offer general-purpose imaging and spectroscopy but has been moved towards wide-field survey science. Especially notable is the major two-degree field (2dF) instrument, which provides simultaneous fiber-based spectroscopy of 400 objects over a 2° field size. The major program for this instrument is a redshift survey of 250 000 galaxies, to greatly improve the knowledge of large-scale structure.

By the late 1970s it was clear that Australia needed increased capability for high-angular-resolution high sensitivity radio imaging and spectroscopy. This need was met by the construction of the Australia Telescope (AT) array, opened in 1988. The main component is the AT Compact Array at Culgoora. It is an aperture synthesis telescope of six 22 m antennas, movable to different stations along a 6 km east–west baseline. The array is at present being upgraded to operate at wavelengths as short as 3 mm, by the addition of new receivers, improved antenna surfaces, and a north spur track. The AT is operated as a national facility by the AUSTRALIA TELESCOPE NATIONAL FACILITY (ATNF), a division of CSIRO which was split from the parent radiophysics division for this purpose. There is also a similar 22 m antenna at Mopra near Coonabarabran, used for VLBI or for stand-alone programs. Australian industry gained a valuable spin-off from the AT project: the company which constructed the antennas has gone on to win contracts for satellite ground station antennas in Australia and South-East Asia. A well-known earlier spin-off, also from radio astronomy, was the Interscan aircraft microwave landing system.

The ATNF also operates the Parkes 64 m dish telescope, which has been upgraded over the years in order to remain competitive. Recently, a multibeam system with 13 simultaneous feeds at 21 cm has commenced operation and is being used for an H I survey of the entire southern sky out to a radial velocity of 12 700 km s^{-1}.

Astronomy at diverse institutions

Other radio astronomy facilities include the University of Tasmania's 26 m paraboloid located at Mt Pleasant near Hobart and ex-Telstra 30 m antenna at Ceduna in South Australia. Both antennas are used primarily for VLBI, in combination with the AT Compact Array and the telescopes at Parkes and Mopra. This university also operates several optical and cosmic ray telescopes. A number of other university groups are active in astronomy, either using national facilities (e.g. Universities of Melbourne and Western Sydney and Macquarie University) or with their own instruments (e.g. the University of Adelaide work on high-energy cosmic rays, the University of Western Australia's development of gravitational wave detectors and the Australian Defense Force Academy's balloon-borne telescopes). Australian astronomers also make considerable use of overseas facilities and satellite observatories including the HST, and strong international collaboration sees some 350 overseas astronomers visiting Australia each year.

The major new optical telescope of the 1980s is the 2.3 m telescope built by MSSSO at the Siding Spring site. Like virtually all modern large telescopes, it uses an alt–az mounting to reduce the expense of the enclosure building. An early notable result obtained with this telescope was the demonstration that the Small Magellanic Cloud is split along the line of sight into two fragments, probably as a result of a collision with the Large Magellanic Cloud some 300 million yr ago. Another major facility at Siding Spring Mountain is the 1.2 m Schmidt telescope, originally a purely UK operation, but merged with the AAO since 1988. This telescope is well known for its high-quality photographic surveys of the southern sky. As well as continuing large surveys and smaller photographic projects, the telescope is also being used for multifiber spectroscopy within the 6° field.

Future opportunities

Australian astronomers have recognized the need for access to an 8 m class optical–INFRARED TELESCOPE in order to remain competitive in the current environment. As a result Australia has joined the international Gemini project as a partner at the 5% level. This will give Australian observers access to both the northern and southern hemispheres, with a variety of high-quality optical and IR instrumentation. However, with an allocation equivalent to 10% of a single telescope, as compared with 50% of the AAT during the era in which 4 m class telescopes led the field, access to 8 m time will be severely limited. Thus it will be vital that the AAT be maintained with a high standard of competitive instrumentation.

Several other development initiatives are worthy of note. Australian astronomers are active in the development of Antarctica as an observing site. The low temperatures and minimal atmospheric water vapor give exceptionally good conditions for infrared observations, including wavelengths that are not normally observable from the ground. There is also the possibility that the high Antarctic plateau may have the best SEEING of any ground-based site. The Joint Australian Center for Astrophysical Research in Antarctica (JACARA), based at the University of New South Wales, is already operating a 60 cm infrared telescope at the South Pole. It is planned to move the telescope at a later date to one of the probably superior (but less accessible) sites on the high plateau.

In radio astronomy, Australia is actively participating in the planning and development of the square kilometer array, an international project aimed at a cm wavelength radio telescope with sensitivity 1–2 orders of magnitude beyond any current instrument. One of the primary astrophysical goals would be the detection and study of the 21 cm emission from neutral hydrogen at high redshifts, in protogalaxies and star formation regions. Subsections of the array would extend over hundreds of km, and one

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the best prospects for an interference-free site of the required size is in the western desert areas of Australia.

Organization

In 1989 a report into astronomy in Australia noted a weakness in theoretical astrophysics. This area was strengthened at the start of the 1990s by the establishment of the Research Center for Theoretical Astrophysics (RCfTA) at the University of Sydney, and later the Australian National University Astrophysical Theory Center in Canberra. Both groups are able to take advantage of the mutual benefits derived from having theoreticians working in close contact with observers. The RCfTA has been created with the financial support of the Australian Research Council (ARC), which disburses government funds in a wide range of scientific and technological areas. Through its grant schemes the ARC also supports much of the observational research work carried out in Australian universities.

The professional astronomical community in Australia consists of some 200 positions, with about 30 of those being fixed-term appointments. There are about 75 PhD students in the various universities nationwide, with about 15 graduating each year. The main association for professional and student astronomers is the ASTRONOMICAL SOCIETY OF AUSTRALIA (ASA), with around 300 members. The principal activities of the ASA comprise organization of annual scientific meetings, management of the publications of the ASA and representation of astronomers' interests to government and the community at large. Official liaison with government is provided by the National Committee for Astronomy (NCA), which operates under the auspices of the Australian Academy of Science. The NCA manages Australia's relations with the INTERNATIONAL ASTRONOMICAL UNION (IAU), and Australia currently has 190 IAU members.

Axis (pl: axes)

A reference line in space or drawn through a body. Usually this is a line about which a body has some degree of symmetry, for example, a line passing through the center of a sphere or which runs centrally through the length of a cylinder. For an ellipse the major axis is a line passing through the center and crossing the greatest diameter of the figure.

The axis of rotation is a real or imaginary line passing through a body, around which that body rotates.

The axial period is the period of time taken for a body to complete one rotation on its axis. The period is usually referred to rotation relative to the stars, in other words, the sidereal rotation period. Thus the axial period of the Earth is 23 h 56 m, although the mean solar day consists of 24 h.

Azimuth

The angle, measured parallel to the horizon in a clockwise direction from north, between the meridian and a celestial body. It is the angle between the north point of the horizon and a point on the horizon vertically below the celestial body.

Azimuth may take any value between 0° and 360°. In some textbooks, azimuth is defined as being measured clockwise from north from 0° to 180° if the object is east of the meridian, and anticlockwise from north from 0° to 180° if the object is west of the meridian. Together with a value of altitude, this specifies the position in the sky of a celestial body as seen at a particular instant from a particular point on the Earth's surface.

For non-astronomical purposes, azimuth (or bearing) is generally measured clockwise from due north.

See also: altitude, culmination, horizon, meridian, zenith distance.

Baade, Wilhelm Heinrich Walter (1893–1960)

Astronomer, born in Westphalia, Germany, worked at the Hamburg Observatory and moved to California in 1931. He and FRITZ ZWICKY proposed in 1934 that supernovae could produce cosmic rays and neutron stars. Identifying it as the supernova of 1054, Baade made extensive studies of the Crab Nebula. He studied its polarization (which led to identification of the light from the nebula as synchrotron radiation), its filaments (the out-rushing body of the exploding star) and the nebula's central star, now known to be the pulsar remnant of the supernova explosion. During the Second World War blackouts of the Los Angeles area, Baade, confined as an alien to the astronomer's paradise of an otherwise little used Mount Wilson, used the 100 in telescope to resolve stars in the central region of the Andromeda Galaxy for the first time. This led to his definition of two stellar populations (Populations I and II), to the realization that there were two kinds of Cepheid variable stars, and from there to a doubling of the assumed scale of the universe. With RUDOLPH MINKOWSKI, identified and took spectra of optical counterparts of many of the first-discovered radio sources, including Cygnus A and Cassiopeia A.

Babbage, Charles (1792–1871)

Polymath, eleventh Lucasian Professor at Cambridge. Known not only for work on astronomy but also in cryptanalysis, probability, geophysics, altimetry, ophthalmoscopy, statistical linguistics, meteorology, actuarial science, lighthouse technology, the use of tree rings as historic climatic records, magnetism, biology, geology, religion, submarines, politics, economics and mathematics. Most important for astronomy, he developed calculating engines (the precursors of modern computers), for the development of which he was unable to obtain funding from the government after Airy's assessment that they would be worthless. One of the founders of the [Royal] Astronomical Society in 1820 and awarded its first Gold Medal.

Babcock, Harold Delos (1882–1968) and Babcock, Horace Welcome (1912–)

Harold was a physicist, born in Edgerton, WI. Became one of the first staff members of the Mount Wilson Observatory, working on precise laboratory studies of atomic spectra, improved the precision of the wavelengths of some 22 000 lines in the solar spectrum, and with Horace, measured the distribution of magnetic fields over the solar surface. He measured the magnetic field of the star 78 Virginis, invented the solar magnetograph, and ruled excellent large gratings, including those used in the coudé spectrographs of the 100 and 200 in telescopes. His son Horace, born in California, also became a staff member of the Mount Wilson Observatory. He not only worked with his father on observational astronomy but also built astronomical instruments, including a ruling engine that produced excellent diffraction gratings, the solar magnetograph, and microphotometers, automatic guiders and exposure meters for the 100 and 200 in telescopes. By combining his polarizing analyser with the spectrograph he discovered magnetic fields in other stars.

Babylonian Astronomy

The civilizations of Mesopotamia nurtured a rich astronomical tradition for about two thousand years, from the early 2nd millennium BC—if not before—until the 1st century AD. Incited by the belief that events seen in the sky were portents signifying future mundane conditions, Babylonians and Assyrians evolved an intricate practice of omen watching, from which they learned the varieties of celestial phenomena and devised rules for predicting their occurrence. From the 7th century BC on, records were kept at Babylon of observations of the Moon, the five visible planets and the Sun. The Babylonians discovered not only the periodic nature of many of the phenomena that they observed, but also that certain phenomena involved several periodic components, which they succeeded in isolating, measuring and finally mimicking by means of arithmetical sequences. Thus arose a mathematical astronomy that operated on quite different principles from the geometrical models of Greek and MEDIEVAL ASTRONOMY. Notwithstanding this disparity of methods, the influence of Babylonian astronomy on its Greek counterpart was deep, and some elements of Babylonian origin persisted in living astronomical traditions across Eurasia through the Middle Ages and into modern times.

Sources

Almost all that we know about Babylonian astronomy is derived from contemporary documents written in the Akkadian language and cuneiform script on clay tablets. Cuneiform tablets were recovered in abundance in excavations in the mid-19th century, and the decipherment of the script followed soon after. The texts that have to do with astronomy number in the thousands. A large and growing fraction of them are available in editions and translations into modern languages, but there are still numerous unpublished tablets, especially among the omen texts and observational records.

The tablets held in modern museums and other collections were only in part obtained by scientific excavations that provided a record of their provenance, the rest having been purchased from dealers. Nevertheless, most of the astronomical tablets can be traced to three sites: the royal library and archive of the Assyrian capital Nineveh, the most important source for texts pertaining to celestial omens, chiefly dating to the first half of the 7th century BC, tablets from uncertain locations in Babylon, almost the sole source for observational records, and also rich in mathematical astronomy, and a temple archive from the southern Babylonian city Uruk, which is the source for the remainder of the mathematical texts.

Before the modern decipherment of cuneiform, practically the only information available about astronomy in Mesopotamia consisted of scattered statements in classical Greek and Latin authors. These range from patently absurd claims of thousands of years of observations to specific technical data that have been triumphantly confirmed from the Babylonian tablets. The diffusion of Babylonian methods and concepts can now be traced more fully in Greek and Egyptian astronomical papyrus fragments from Roman Egypt and in certain Indian astronomical texts.

Astronomy in Mesopotamian omen lore

Celestial omens constituted a large part of the vast repertoire of events regarded by the Mesopotamians as ominous. The belief in omens was essentially religious: the gods, it was supposed, gave humans notice of their mood and intentions through visible signs, which it was the business of expert diviners to interpret. Omen texts, typically expressed as conditional sentences linking a portent to a predicted outcome (e.g. 'If the moon at its appearance glides through clouds: the flood will come'), were collected in compendia such as the series of celestial omens *Enūma Anu Enlil* ('when the gods Anu and Enlil', from the opening words), which comprised some 70 tablets. *Enūma Anu Enlil* survives in fragmentary copies from the 7th century BC and later, but some celestial omens both contained in this collection and preserved outside it date from the first half of the 2nd millennium BC, and a small number refer to historical events of the 3rd millennium.

The omens of *Enūma Anu Enlil* are, in the broadest sense, 'sky omens', encompassing meteorological phenomena as well as sightings of the Moon, the Sun, the five planets and fixed stars. Even in the observation of a heavenly body, color and brightness, halos and attendant weather are treated on an equal basis with times, dates and positions. It would be misleading to call the observational component of this divination astronomy, but much astronomy is latent in it. Thus the aspects of a lunar eclipse that helped to determine its ominous import—generally the death of a king—included the date and rough time of day, the directions from which the Moon's disk was obscured at the beginning and end of the eclipse and occasionally also the constellation within which the eclipse took place.

The archives of the Assyrian kings at Nineveh, now in the British Museum, preserved numerous letters and reports addressed to the kings Esarhaddon (680–669 BC) and Ashurbanipal (668-627 BC) by a network of omen watchers in Nineveh and other Assyrian and Babylonian cities. In this fascinating correspondence we can see that a vigilant watch on the Moon, Sun and planets was a matter of the highest political importance, affecting decisions concerned with all the king's actions. The scholars on whom the king depended had the best motives for seeking to know in advance when ominous phenomena could be expected or ruled out: colleagues were always at the ready to point out to the king a mistaken or late sighting.

Forecasts, which are frequent in the royal correspondence, chiefly concern lunar and solar ECLIPSES and the first visibilities of planets. Typical forecasts are either confidently negative ('an eclipse will not occur this month', or 'a specific planet's appearance is not imminent') or conditionally affirmative ('if an eclipse will occur this month, we should watch for it at a particular time of day or night').

Dirac House, Temple Back, Bristol, BS1 6BE, UK

In addition to divinatory methods, which can hardly have been reliable, the omen watchers seem to have depended on knowledge of the approximate possible intervals between eclipses and between successive appearances and disappearances of the planets. Whether they also made use of longer periodicities is not known.

MUL.APIN ('Plough Star') is the most important of a handful of texts from the 2nd and early 1st millennium BC that are concerned primarily with genuine astronomical topics. The longest part of this compilation consists of lists of constellations and stars, bearing more or less pictorial names such as the 'wagon', the 'frond of Eru' and the 'hired man'. Stars that rise and set are grouped in three 'paths', apparently according to the parts of the eastern horizon that they rise within, but no further attempt is made to describe their arrangements or locations. Astronomical tests are given for determining when an intercalary month should be inserted in the lunar calendar to keep it in line with the seasons. *MUL.APIN* contains little lunar astronomy, and its treatment of the planets is limited to rough estimates of the intervals of time between appearances and disappearances.

A second text of great interest is the fourteenth tablet of *Enūma Anu Enlil*, which, unlike the rest of the compilation, is not a collection of omen texts, but a set of tables of numbers. One of these tables represents the varying duration of nocturnal lunar visibility through the course of a synodic month on the assumption that the length of night is at its maximum, i.e. close to winter SOLSTICE, and a second table represents, month by month through a schematic solar year, the daily change in the duration of nocturnal lunar visibility. Except at the beginning and end of the first table, where a curious pattern of constant second differences is used, the numbers increase to a maximum and thereafter decrease again by constant differences, a kind of sequence that is called by modern authors (from its appearance when graphed) a linear zigzag function. Simple zigzag functions consisting of small whole numbers are an obvious means of describing a periodically varying quantity, and the oldest known example is a crude table representing the varying length of daylight through the year in a second millennium BC papyrus from Egypt, a land not noted for its mathematical astronomy. What is remarkable here is that by about 1000 BC, Mesopotamian astronomers were attempting to isolate, and present mathematical models for, two independent periodic elements in a phenomenon that oscillates in a complex way.

Diaries and Goal Year Texts

The extent to which omen watchers maintained records of what they saw in the heavens is not known. In at least one city, Babylon, a group of scribes who may or may not have been omen watchers had already begun by the middle of the 7th century to record a remarkable variety of dated phenomena in tablets that we now call Diaries. Many hundreds of fragments of Diary tablets from Babylon survive, pertaining to years ranging from 652 to 61 BC, with the bulk of them coming from the last three centuries BC. Typically a Diary tablet covered half a lunar year, that is, six or seven lunar months. For each month, night by night and day by day, the Diary records observations of the heavenly bodies and weather, and each month ends with records of commodity prices, the level of the Euphrates River, and current events.

The most conspicuous object in the Diaries is the Moon. Every month, six time intervals (the 'Lunar Six') were measured in units called *uš* or 'time-degrees', such that 360 time-degrees equal one (mean) day from sunset to sunset:

1. sunset to moonset on the evening of first lunar visibility;
2. moonset to sunrise on the morning before full Moon;
3. moonrise to sunset on the evening before full Moon;
4. sunrise to moonset on the morning after full Moon;
5. sunset to moonrise on the evening after full Moon;
6. moonrise to sunrise on the morning of last lunar visibility.

This is an extension of the interest in lunar nocturnal visibility evinced in *Enūma Anu Enlil* tablet 14. Also recorded with great frequency in the Diaries are the Moon's passages by about 30 bright stars close to the ECLIPTIC, known as Normal Stars. The circumstances of lunar and solar eclipses are given in detail.

For the planets, the Diaries record passages by the Normal Stars and close approaches to each other, and also certain events in their synodic cycles (see SYNODIC PERIOD. The reported synodic phenomena of Saturn, Jupiter and Mars are their first visibilities and disappearances, stations, and acronychal (sunset) risings. First visibilities and disappearances as morning and evening star are reported for Venus and Mercury. The locations of the planets at their synodic phenomena are specified, if at all, only roughly in relation to a constellation, or, in later Diaries, by the zodiacal sign occupied by the planet. The transition from constellations to conventional zodiacal signs covering equal twelfths of the ecliptic seems to have taken place about the middle of the 5th century BC.

Many entries in the Diaries are not observations. Predicted or corrected data are recorded where weather delayed or obstructed observation, often accompanied by the remark, 'I did not watch'. The sources of many of these predictions have not been established beyond dispute. One important method of forecasting planetary and lunar phenomena was certainly the application of the 'Goal Year periods'. These were periodicities ranging from as few as 8 yr for Venus to as many as 83 yr for Jupiter, after which an approximate repetition of phenomena (synodic events or Normal Star passages) takes place. The planetary periods are all whole numbers of solar years. The important periodicity for the moon was the so-called 'SAROS', an eclipse period comprising 223 synodic months (about 18 yr) that also contains close to a whole number of periods of lunar anomaly and lunar latitude. In tablets called Goal Year Texts, observation reports extracted from the Diaries one Goal Year back are collected to provide the

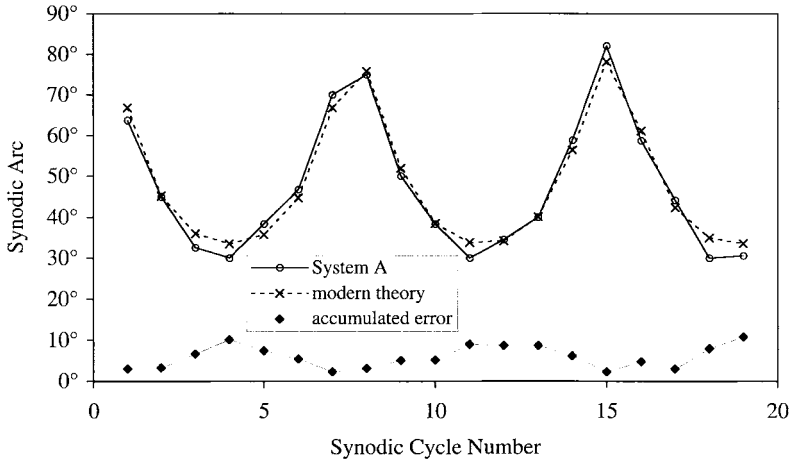

Figure 1. Predictions of longitudes of Mars' first stationary point by system A.

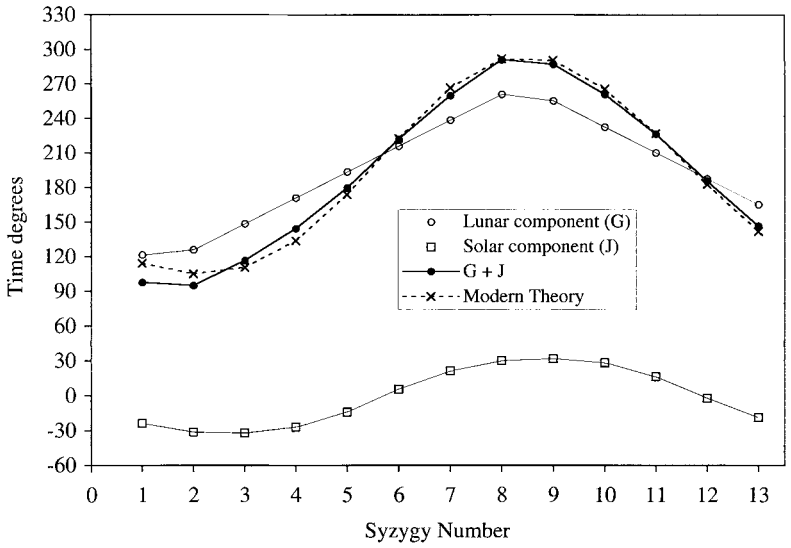

Figure 2. Predictions of lengths of synodic months by system B.

basis for predictions for an approaching year. To make the actual predictions, corrections would have to be applied to take account of the inexactness of the periodicities. Tablets known as Almanacs and Normal Star Almanacs, containing predictions of certain categories of Diary-type phenomena for a specific year, are likely to be the products of this process.

Mathematical astronomy

The primary goal of Babylonian mathematical astronomy was to calculate certain of the phenomena that the Diaries recorded. These included the dates and longitudes of the synodic phenomena of the planets, the 'Lunar Six' time intervals and eclipses. The predictions were achieved by means of sequences of numbers generated arithmetically according to rules such that each sequence would repeat with exactly the periodicity required for a particular component of the motion of a heavenly body. The predictive models fall into two categories. Models in which linear zigzag functions are prominent among the sequences are referred to as system B models. Those in which the numbers follow 'step functions' depending numerically on the location of the heavenly body within partitions of the ecliptic are called system A models. System A and system B models were used concurrently at both Babylon and Uruk.

The planetary models work with 'synodic arcs', the numbers of degrees by which a planet progresses through the ecliptic from one occurrence of a synodic phenomenon to the next occurrence of the same phenomenon, and 'synodic times', the numbers of months and days from one event to the next. The actual longitudes (degrees within zodiacal signs) and dates of phenomena are obtained as the running total of the synodic arcs and times, which are

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

generated as periodic sequences. The periodicity can be expressed by the equation

$$\Pi \text{ occurrences} = Z \text{ revolutions of the ecliptic} = Y \text{ yr}$$

where Π, Z and Y are whole numbers, and Π and Z are relatively prime. Thus in a table of planetary phenomena predicted according to a Babylonian model, after Π lines the longitude will return exactly to its original value.

System A planetary models employ rules equivalent to the following assumptions: (1) the ecliptic is divided into two or more zones with fixed boundaries, (2) the Π occurrences of a phenomenon within a full period of Y yr are distributed along the ecliptic such that they are spaced at equal intervals inside each of the zones and (3) the progress from one occurrence to the next is Z intervals. The Babylonian base 60 place-value notation for numbers introduces some nonastronomical restrictions on the model, since one always wants the calculations to lead to numbers that terminate after a small number of fractional places, usually two. Nevertheless, the sequence of synodic arcs can be shaped by a suitable choice of parameters so as to reproduce successfully the actual behavior of a planet, as is illustrated by figure 1, in which a run of synodic arcs between first stationary points of Mars calculated by the system A model is compared with the same intervals computed by modern theory. System B, according to which the synodic arcs and times are zigzag functions, is a more restrictive model, and less successful in reproducing the phenomena.

A complete table of computed phenomena for a planet might contain columns giving the dates and longitudes of the full cycle of synodic phenomena, for example Mars' first visibility, first station acronychal rising, second station, and disappearance. Longitudes on intermediate dates could be obtained by extrapolation from or interpolation between the tabulated date–longitude pairs.

The Babylonian lunar models are a more remarkable achievement than the planetary models. Eclipses and lunar visibility times are affected by several independent periodic components, which it cannot have been easy to isolate and measure. In the system A and system B models, at least four periodicities are present: the year (apparently no distinction was drawn between sidereal, tropical, and anomalistic years), the synodic month and the periods of lunar anomaly and latitude. The calculation of the precise time of conjunction may serve to illustrate the approach. The interval between the preceding and current conjunction is assumed to be 29 days plus two variable components (expressed in time-degrees), called J and G. G varies with the Moon's anomalistic period. In system B it is a linear zigzag function, while in system A it is a zigzag function 'snubbed' into a sinusoidal shape at its extrema by second-order arithmetical sequences. J has the solar year for its period. It is modelled in system A by a step function dependent on the Sun's longitude, whereas in system B it is a smooth sinusoidal sequence obtained as the running total of a linear zigzag function. Figure 2 shows a run of values of G, J and their sum from a system B tablet. The errors in the calculated times, which can be as large as 2 h, are due partly to the use of fairly simple arithmetical functions and partly to the inherent inaccuracy of representing the true synodic month as the sum of two independent periodic functions. The periodicities, especially those of the system B lunar theory, are very accurate.

The last tablets of Mesopotamian astronomy are almanacs from the AD 70s. By that date, however, the methods of Babylonian mathematical astronomy had spread to the Greek-speaking world, where they provided the computational foundation for Greco-Roman ASTROLOGY until they were superseded by Ptolemy's tables in late antiquity. HIPPARCHUS and PTOLEMY used Babylonian observation reports and the periodicities of the system B lunar theory, and their work may have been influenced less directly by other aspects of the mathematical models.

Backlund, Jöns Oskar (1846–1916)

Born in Sweden, worked in Russia, at the Dorpat (now Tartu) Observatory, became director of Pulkovo Observatory, and the Imperial Academy of Sciences in Petrograd. He employed a large staff to compute the orbit of Comet Encke, eventually concluding that the comet's motion was affected by non-gravitational forces (now known to be light pressure and magnetic forces from the Sun).

Bailey, Solon Irving (1854–1931)

American astronomer, born New Hampshire. Discovered the variable stars in globular clusters now known as RR Lyrae variables, and divided them into classes a, b and c, according to the shapes of their light curves, now known to be an indication whether the star is pulsating in the fundamental mode or an overtone.

Baillaud, Édouard Benjamin (1848–1934)

French astronomer, became director of Toulouse Observatory and Paris Observatory. He worked in celestial mechanics, especially on the motions of the satellites of Saturn, and inaugurated the telegraphy of time signals from the Paris Observatory via the Eiffel Tower. First president of the International Astronomical Union.

Bailly, Jean Sylvain (1736–93)

Astronomer and politician, born in Paris, studied Halley's comet and the satellites of Jupiter, wrote *Histoire de l'Astronomie*. Guillotined as the result of an incident when, as Mayor of Paris during the Revolution in 1789, he let the National Guard fire on republican crowds. Unfortunately not the only astronomer to be executed—see ARCHIMEDES, GIORDANO BRUNO, HYPATIA OF ALEXANDRIA, ULUGH BEG, who represent nearly 1% of the astronomers whose biographies are in this encyclopedia; perhaps astronomy is a riskier profession than one would think!

Baily's Beads

Brilliant points of light seen at the edge of the Moon's disk during a total eclipse of the Sun, just at the onset and termination of totality. They are due to sunlight passing through valleys and indentations at the edge of the Moon's visible disk. The English astronomer Francis Baily (1774–1844) drew attention to the phenomenon during the solar eclipse of 1836.

Banneker, Benjamin (1731–1806)

The 'Sable Astronomer', first black American scientist, born in Ellicott's Mills, MD of a family of former slaves. As a young man, Banneker borrowed a pocket watch, took it apart, made a drawing of each component, and reassembled it; after which he made out of wood a working, enlarged replica which lasted over 50 years. At age 58, he began the study of astronomy and was soon predicting eclipses. He compiled this information, including other astronomical and tide calculations, weather predictions, proverbs, poems and essays contributed by himself and others into *Benjamin Banneker's Almanac* (1792–1802). This almanac was cited by opponents of slavery (including Thomas Jefferson) as evidence of African-Americans' abilities.

Bappu, Manali Kallat Vainu (1927–82)

Born in Hyderabad, India, of an astronomer father, and became director of the Kodaikanal Observatory. Following a chance meeting with SIR HAROLD SPENCER JONES and HARLOW SHAPLEY, enrolled in Harvard, was co-discoverer of comet Bappu–Bok–Newkirk. Working with OLIN WILSON at the Mount Wilson Observatory, Bappu discovered that for stars of spectral types later than G0 there is a relationship between their luminosities and the characteristics of the H and K emission lying in the absorption lines of singly ionized calcium. The reason was that the emission is characteristic of the surrounding atmosphere of the star, which is related to its size and thus to its luminosity. This phenomenon, is known as the *Wilson–Bappu effect*, and is a method to determine the absolute magnitudes, and therefore the distances, of late-type stars. He returned to India where he set up a modern astronomical observatory at Nain Tal in Uttar Pradesh. The Vainu Bappu Observatory is the main optical observatory of the Indian Institute of Astrophysics, located in the state of Tamil Nadu.

Barlow Lens

An additional lens that increases the effective focal length and magnification of a telescope. It is a negative diverging lens (either concave on both sides or, more usually, 'plano-concave'—flat on one side and concave on the other) that is placed in the converging cone of light a short distance in front of the focal plane of the objective or primary mirror. By decreasing the angle at which the light rays are converging, it increases the effective focal length of the telescope, so enabling a given eyepiece to achieve a higher magnification. The amplification factor (the ratio of the effective focal length of the objective with the Barlow lens in place to the focal length of the objective alone) of a Barlow lens of focal length f_b, placed a distance d inside the focal plane of an objective, is $f_b/(f_b - d)$. For example, if a Barlow lens with a focal length of 100 mm is placed 50 mm inside the focus of the objective, the effective focal length will be increased by a factor of $100/(100 - 50) = 100/50 = 2$.

Barlow, Peter (1776–1862)

Nautical engineer, born in Norwich, Norfolk, England, professor of mathematics in the Royal Military Academy, Woolwich, where he worked on the strength of ships' timbers, tidal engineering and ships' magnetism. His best known publication is *New Mathematical Tables*, giving the factors, squares, cubes, square and cube roots, reciprocals and hyperbolic logarithms of all numbers from 1 to 10 000, together with the powers of numbers up to 1000. The tables were widely used for navigation and astronomy. His optical experiments began about 1827, and with George Dollond he invented the *Barlow lens*, a concave achromatic lens used to magnify the image produced by a telescope, and employed first to measure close double stars (also used in photography).

Barnard, Edward Emerson (1857–1923)

Astronomer, born in Nashville, Tennessee. As a poor photographer's assistant he made his own telescope and discovered several comets. During this time, a wealthy patron of astronomy awarded $200 each time a new comet was found, and Barnard's eight comets earned enough to build a house for his bride and led to his gaining an education at Vanderbilt University and joining the initial staff of the Lick Observatory. In 1895 he moved to the new Yerkes Observatory. He discovered *Barnard's Star* (the star with the largest proper motion, and one of the nearest stars), Jupiter's satellite Amalthea, and, by wide-field photography, dark clouds and globules in the Milky Way, including *Barnard's Loop* around Orion.

Barnard's Loop (Sh2-276)

A large emission nebula in the constellation Orion in the form of an arc centered on the Sword of Orion; the midpoint of the arc is at approximately RA $05^{h}\,56^{m}$, dec. -02°. The emission is thought to be caused by radiation pressure from the hot stars in the Sword region ionizing interstellar matter. It was discovered by E E Barnard.

Barnard's Star

A noteworthy star in the inconspicuous constellation Ophiuchus, it lies about 34° south of Vega and 28° west of Altair. It is identified only by a catalog designation, e.g. BD+4°3561. Despite being very faint, apparent magnitude 9.54 and hence visible only with powerful binoculars or a small telescope, it has several claims upon our interest. With a parallax of 0.549″, at a distance of 5.9 light-years, only the triple system of Alpha Centauri is closer to us. Discovered in 1916 by the great American observer Edward Barnard (1857–1923), it soon became clear that this star has the largest known proper motion, 10.36″ per annum. This so-called 'fixed star' is moving across the sky through a distance equivalent to the Moon's diameter every 174 years.

It is a red subdwarf star, spectral type sdM4, of very low intrinsic luminosity (absolute magnitude 13.2). A study of its observed motion by Peter van de Kamp (b. 1901) suggested that it is subject to regular, small fluctuations in both right ascension and declination, suggesting that its motion is perturbed by the presence of a binary companion too faint to be separately observed. Van de Kamp estimated that this companion might well be a non-luminous body of mass about 1.6 times that of Jupiter, i.e. a planet. This was the first well-documented case of this kind but has not been confirmed.

Barred Spiral Galaxy

A galaxy in which the spiral arms emerge from the ends of a bar or elongated ellipsoid of stars that straddles the nucleus rather than from the nucleus itself. Barred spiral galaxies, denoted by 'SB' in the Hubble classification scheme, are classified according to the size of the central bulge, the tightness of the spiral pattern and the degree of clumpiness in the arms.

The central bulge of our own galaxy, the Milky Way, appears to be an elongated ellipsoid that is seen almost end-on from the present location of the Sun. Consequently, there are grounds for classifying it as a barred spiral.

Barringer, Daniel Moreau (1860–1929)

A Philadelphia mining engineer who, in 1903–5, investigated the 'Coon Butte' crater in Arizona, in pursuit of the theory that it was of meteoritic origin. Before he realized that the impact was oblique and the meteor was off-center, he unsuccessfully searched for a buried mass of nickel and rare-earths by drilling in the crater bottom. He collected meteoric iron fragments, which he noticed were intermixed with terrestrial rock fragments, and used this as evidence of his theory that the crater had been made by a meteor impact. He identified geological evidence of the shock that had excavated the crater, such as pulverized silica and a type of quartz glass, later called lechatelierite. Barringer's scientific conclusion about the origin of the crater was eventually shown by FOREST RAY MOULTON, HENRY NORRIS RUSSELL and HARLOW SHAPLEY to be correct. However, as a result of his theory being proved, it was concluded that what he had thought was a valuable lode of nickel was not only off-center, but smaller than he had at first estimated and would have vaporized on impact. The directors of the mining company which supported his work withdrew funding and Barringer died of a heart attack within weeks. The crater is now referred to as the *Barringer Meteor Crater*, the first terrestrial crater recognized to be of meteoritic origin.

Barycenter

The center of mass of the Earth–Moon system or any other set of bodies (e.g. the solar system). If two bodies move under the influence of their mutual gravitational attractions, they will describe orbits around a point between them, the center of mass of the two bodies. The relative distances of the two bodies from this point will be inversely proportional to their masses. Thus, for example, if one body is twice the mass of the other, the center of mass will lie one-third of the way from the more massive body to the less massive one (i.e. their distances are in ratio 1:2).

In the case of the Earth and Moon, the ratio of masses is approximately 81:1. The barycenter is therefore located at a distance from the Earth's center equal to 1/82 of the distance from the Earth to the Moon, and on the line joining the centers of Earth and Moon, in other words at a distance of about 4700 km from the center of the Earth. The point is, in fact, located *within* the Earth. The distance between the centers of the Earth and the Moon varies rather widely due to the combined gravity of the Earth, the Sun and the planets. For example, during the period 1969–2000, apogee (the greatest distance) varies from 404 063 to 406 711 km. Perigee (the least distance) varies from 356 517 to 370 354 km. This has a proportionate effect on the distances of the centers of the Earth and the Moon from the barycenter.

Baryogenesis (baryon genesis or matter/antimatter asymmetry)

Associated with every type of particle there is an ANTIMATTER particle with the opposite quantum numbers. For example, the positron (charge +1) is the antiparticle of the electron (charge −1), and the antiproton (charge −1, baryon number −1) is the antiparticle of the proton (charge +1, baryon number +1). Particles can annihilate with their antiparticles into radiation, and particle–antiparticle pairs can be created from the vacuum.

Observations seem to suggest that the universe consists of matter, with no appreciable amounts of antimatter. Domains of antimatter galaxies and antimatter galaxy clusters, if they exist, must be widely separated. The simplest explanation is that there is an antimatter asymmetry in the universe: today the universe consists solely of particles with no large antimatter systems.

The matter/antimatter asymmetry is usually expressed in terms of a dimensionless number known as the 'baryon number of the universe'. If a baryon number of +1 is assigned to BARYONS (neutrons, protons and the more massive baryon resonances) and a baryon number of −1 assigned to antibaryons, then because of the absence of large amounts of antimatter, the present baryon number density (baryon number density minus the antibaryon number density) can be expressed in terms of the total mass density of the universe. The baryon number is the ratio of the baryon number density to the entropy density of the universe. With an uncertainty of a factor of three to five, the baryon number of the universe is about 10^{-10}.

So long as baryon number is conserved in every individual reaction and the expansion of the universe is isentropic (entropy conserving), the baryon number of the universe is conserved over the history of the universe.

Although there is no antimatter in the universe today, if the temperature of the universe was ever larger than about 10^{13} K, and thus its thermal energy exceeded the rest-energy of the proton, then antimatter would have existed in great abundance. Earlier than about a millisecond after the BIG BANG the universe should have been hot enough for the radiation to create particle–antiparticle pairs. If the baryon number is conserved, then at sufficiently high temperature a baryon number of 10^{-10} implies that there were roughly equal numbers of baryons and antibaryons in the universe, but for every 10 billion antibaryons there were 10 billion and one baryons. As the universe cooled below the temperature required to produce proton–antiproton pairs from the radiation, all of the antibaryons annihilated, leaving behind the excess baryon number of 1 part in 10 billion. While such a tiny asymmetry between the number of baryons and the number of antibaryons might seem insignificant, without the asymmetry all of the baryons and antibaryons would have annihilated, resulting in a universe without the matter (or antimatter) required to form galaxies, stars and planets.

While the present baryon number of the universe may simply reflect an initial condition of the big bang, it seems more natural that a universe with zero baryon number, as would result if the universe underwent a period of 'INFLATION', evolved into a universe with a small baryon number.

In 1967, the Russian physicist Andrei Sakharov outlined the three 'ingredients' necessary to generate a baryon asymmetry from initially symmetric conditions. The first requirement is that some particle reactions must violate baryon number. The second condition is a violation of CP symmetry (charge conjugation times parity). Finally, baryogenesis requires a departure from local thermodynamic equilibrium.

These three Sakharov ingredients may have been present in the early universe. The expansion of the universe can lead to nonequilibrium conditions. CP violation was discovered in 1964 by James Cronin and Val Fitch in reactions involving particles known as kaons. While violation of baryon number has never been observed, it is predicted to occur in several theories. The different possibilities for baryon-number violation have resulted in the development of different scenarios for baryogenesis.

In theories of the unification of the strong weak, and electromagnetic interactions into a GRAND UNIFIED THEORY (GUT), baryon number is predicted to be violated by the decay of supermassive particles of mass as large as 10^{16} times the mass of the proton. In the simplest versions of GUT baryogenesis, the supermassive particles were present in the thermal radiation, and as the temperature of the universe fell below the equivalent mass of the supermassive particle, they decayed preferentially into baryons. In the GUT scenario, baryogenesis occurred 10^{-35} seconds after the bang.

Unification of the electromagnetic and weak interactions involve a breaking of the electroweak symmetry where the Higgs field acquires a vacuum expectation value. Although broken today, at sufficiently high temperatures the symmetry should be restored. A phase transition associated with the breaking of electroweak symmetry is expected as the temperature of the universe fell below about 10^{15} K. Nonperturbative baryon-number violating processes are predicted to operate above the phase transition. A scenario of electroweak baryogenesis has been developed where the baryon asymmetry is generated around the time of the electroweak phase transition, around 10^{-12} seconds after the bang.

SUPERSYMMETRY theories have bosonic partners for the quarks and leptons. These particles, known as squarks and sleptons, are bosons, and may develop vacuum expectation values. Any change in the vacuum expectation value of a squark field results in a violation of baryon number. The age of the universe during baryogenesis is not specified in this scenario.

Other baryogenesis scenarios involve variations or combinations of the three scenarios above. Although the exact mechanism of baryogenesis is still a matter of intense speculation, the three Sakharov ingredients are expected to be present in the early big bang: CP violation has been

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

observed in nature, the expansion of the universe naturally leads to departures from equilibrium, and baryon-number violation is expected to occur in a variety of ways.

Although the details of baryogenesis are unknown, laboratory experiments may help to unravel the mystery. Study of CP violation involving bottom quarks may lead to a deeper understanding of this ingredient. Knowledge of the electroweak Higgs mass is important for electroweak baryogenesis. Discovery of low-energy supersymmetry would have important implications for electroweak baryogenesis, as well as scenarios involving squark expectation values. Finally, observation of proton decay, or other direct evidence for grand unification, would be important for GUT baryogenesis scenarios.

Baryons

Subatomic particles that are composed of three quarks and which are acted on by the strong nuclear force. This class of particle includes the nucleons (protons and neutrons), which are the constituents of atomic nuclei, and a variety of heavier, but short-lived, particles called hyperons.

Because the mass of a nucleon is nearly 2000 times greater than the mass of an electron, and all atoms and molecules contain at least as many nucleons as electrons, baryons account for more than 99.5% of the total mass of all the chemical elements in the universe. Matter that is composed of baryons is known as 'baryonic matter'. If the mean density of the universe is sufficiently high to ensure that it is 'closed' (a closed universe eventually ceases to expand and then collapses) or 'flat' (a flat universe is just, but only just, capable of expanding forever), at least 90% of it must exist in the form of dark, non-baryonic, matter, the nature of which is not yet known.

Bayer, Johann (1572–1625)

Lawyer and astronomer, born in Rhain, Germany. His catalog and atlas *Uranometria* (1603) depicts the positions of double the thousand stars in Tycho Brahe's catalog on which it is based, designating the brighter stars by the letters of the Greek alphabet, usually in brightness order, followed by Latin letters. This was instead of Arabic proper names or by AL-SUFI's awkward descriptions relative to the constellation figures, such as 'the star at the tip of the lesser bear's tail'. Bayer's lettering system is still used. Bayer included 12 new southern asterisms to fill in the region of the sky unseen by classical astronomers like PTOLEMY. They were: Apus, Chamaeleon, Dorado, Grus, Hydrus, Indus, Musca (Bayer called it Apis), Pavo, Phoenix, Triangulum Australe, Tucana and Volans, all still in use.

Be Stars

A Be star (pronounced 'bee-ee' star) is a non-supergiant B-type star whose spectrum displays or has displayed one or more Balmer lines in emission and Be is the notation for the spectral classification of such a star (see also CLASSIFICATION OF STELLAR SPECTRA). 'Classical' Be stars are believed to have acquired the circumstellar (CS) material that produces the Balmer emission through ejection of matter from their photospheres instead of from mass ACCRETION, and therefore are regarded as a separate subgroup distinct from the Herbig Be objects and interacting BINARY STARS. For the early B stars in our region of the galaxy, the fraction of Be/B stars is about 20%. This ratio drops to about 10–15% for late B stars and early B stars in the interior of our galaxy. The percentage of Be stars appears to be larger in the MAGELLANIC CLOUDS (25–45%). As a group Be stars are rapidly rotating. Spectral analysis, and more recently interferometric imaging, suggests that the CS material is in the form of a disk positioned about the equator of the star (figure 1). The Be-shell stars are classical Be stars that also exhibit narrow absorption lines, usually from moderately ionized species such as Fe II, as well as central narrow components to the Balmer emission lines that extend below the continuum. The current consensus is that the Be-shell stars are classical Be stars viewed nearly equator on.

The first Be star to be discovered was γ Cas in 1866 by A. Secchi, although this object has not endured as a prototype of the class. Based on the tendency of Be stars to display diffuse, rotationally broadened lines, in 1931 O Struve hypothesized that Be stars are rotating just short of their critical, or break-up, velocities, thus making it favorable for material at the star's equator to slowly dribble off into a CS disk. Although the disk geometry prevails, this model is no longer believed as there is no evidence that any Be star rotates faster than $0.85V_{\rm crit}$. Rapid rotation may play some role in the mass loss process, however. Spectroscopic observations of Be stars since 1980 have revealed that material is ejected from the photosphere, sometimes in a violent manner. An individual star can indeed oscillate between showing Balmer emission and apparently a pure photospheric spectrum. It is now clear that one must consider the star and disk as a whole in order to gain an understanding of what is called the 'Be phenomenon'.

The disk

The hallmark of a Be star is its CS disk that produces the strong Balmer line emission. A simple model for a Be disk is shown in figure 1. In first order, it is the kinematical motion of the CS gas in the disk that broadens the emission lines and gives the generic double-peaked line profile shown in figure 1. The arrows in the disk show the motion of the material and the gray tones map into the emission line profile. Material in the inner disk, where the radial motions toward–away from us are the largest, contribute most of the flux in the wings of the emission profile.

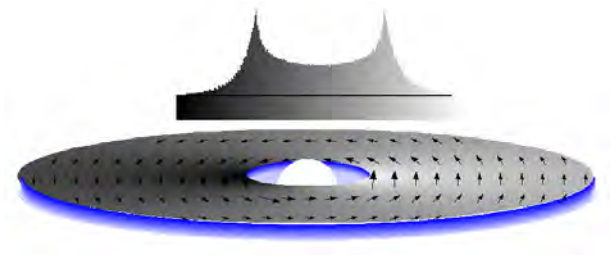

Figure 1. A generic representation of a Be star. A typical Balmer emission feature that the disk would produce is shown above the star. Illustration courtesy of S Owocki.

INTERFEROMETRY and IR photometry (see STELLAR PHOTOMETRY) suggest that the radial extent of the disk is $>20R_*$ and that the material displays Keplerian motion. The vertical extent of the inner disk is calculated from observation and theory in which the disk is assumed to be in hydrostatic balance (justified as disks can be stable for long periods of time). The inner disk appears to have a vertical height of $\sim 1R_*$ (Be-shell stars can show deep shell lines that have residual intensities of <10%), but at large radii the disk can flare to several stellar radii (not shown in figure 1). It is currently unknown whether there is a gap between the disk and the star as depicted in figure 1. Fitting of theoretical disk models to Balmer and Paschen emission lines suggests that the density, N_0, at the inner edge of the disk varies from 10^{12} to 10^{14} cm^{-3} for optically thin/thick disks. The density distribution in the disk is usually assumed to follow the formula: $N_{\rm r} = N_0(r/R_*)^{-m} \exp[-\frac{1}{2}(z/h)^2]$, where z and h are the vertical distance above the disk plane and the scale height, and $2 < m < 3.5$. Temperatures in the equatorial regions of B0–B5e stars range from 8000 to 5000 K and are 2–3 times higher at the upper–lower edges of the disk.

The profiles of emission lines in Be stars assume a variety of shapes both symmetric and asymmetric. When a star shows symmetrical emission lines spectral variablity is minimal, but long-term cyclical variability is commonplace in stars that display asymmetrical emission features. The star's inclination, i, to our line of sight has the greatest influence on the line profile, but the optical depth, τ, in the disk and the overall kinematic motion of the disk material are also important. This allows one to probe the density structure and kinematics in the disk by fitting theoretical profiles to observations of emission lines from ions of widely different abundances (e.g. Balmer and Fe II lines). Some representative Hα profiles of Be stars viewed at pole-on, intermediate and equator-on inclinations are shown in figure 2. The term pole on usually refers to objects with $i < 30°$; for equator-on stars $i > 80°$. Keplerian motion dominates the broadening of the line profile. The kinematical velocity width of the emission line depends on the projected Keplerian velocity, $v_{\rm K}$ (~400–500 km s^{-1}), of the material at the inner edge of the disk, $\Delta v_{\rm kin} = v_{\rm K} \sin i$. High-resolution spectra of Be stars seen at low–intermediate inclinations often reveal inflections,

or shoulders to the Hα or Hβ emission lines (cf. inset to the profile in the upper-left corner of figure 2). This so-called winebottle appearance is a result of non-coherent scattering in an optically thick disk. Photons scattered into the wings of the line deep in the disk readily escape from the star. In the wings of an optically thick emission line one is seeing radiation from deeper in the disk where the source function is larger. For Be stars seen at large inclination angles, such as the Be-shell stars, the absorption of the stars's light as it passes through the disk material produces a deep central reversal in the emission feature.

The Balmer emission lines seen in Be-shell stars frequently undergo long-term (~2–10 yr) periodic or quasi-periodic oscillations in the relative intensities of the violet-shifted (I_V) and red-shifted (I_R) components to the line. These are termed V/R variations, where V and R refer to the emission above the local continuum: $V = I_V - I_{\rm cont}$ and $R = I_R - I_{\rm cont}$. It is currently thought that the V/R oscillations are caused from the precession of a density enhancement or wave in a quasi-Keplerian disk. These global disk oscillations are believed to also cause the long-term profile variations seen in the Be stars with asymmetrical emission lines. A typical example of a long-term V/R variation in Hα in a Be-shell star is shown in figure 2. Variability in the peak intensity of the emission from cycle to cycle is typical.

The wind

The mass flux from the stellar winds in Be stars is generally larger than in non-emission B stars; however, there appears to be a prominent dependence on the inclination of the star to our line of sight. Information on the winds is obtained from observations of the UV resonance lines (e.g. N V λ 1238.8, 1242.8, C IV λ 1548.2, 1550.8, Si IV λ 1393.8, 1402.8, Si III λ 1206.5, and Al III λ 1854.7, 1862.8). N V tends to be observed in only the earliest Be stars. The wind absorption seen in stars viewed equator on or at intermediate inclinations is typically strong and frequently contains discrete absorption components (DACs), while pole-on objects usually show either no or very weak wind features. DACs are discernible absorption features superimposed upon apparently smooth underlying wind lines. These relatively narrow (usually $\Delta V < 200$ km s^{-1}) features are thought to be formed as a result of shocks in the wind. Some typical C IV wind features are displayed in figures 3 and 4. The maximum velocity of the wind absorption is in the range (0.4–2.0$V_{\rm esc}$) and appears to increase toward earlier spectral types.

Although the UV wind features are very prominent, they are actually formed in a region of much lower density than the optical–IR emission lines. The mass loss rates (~$10^{-10} M_\odot$ yr^{-1}) computed from the UV wind lines are about 50–100 times smaller than those determined from IR photometry and fitting of the optical–IR emission lines. It is currently believed that the high-velocity, low-density stellar wind flows out of the equatorial plane toward intermediate latitudes and has very little influence on the more massive Keplerian disk.

Variability is commonplace in the winds of Be stars, both short and long term. Examples are shown in figure 3 and figure 4 for winds with and without DACs. The upper panel in each figure shows a Be star that displays daily, cyclical wind variations, while the lower panel illustrates typical long-term (yearly) quasi-cyclical variations. Most

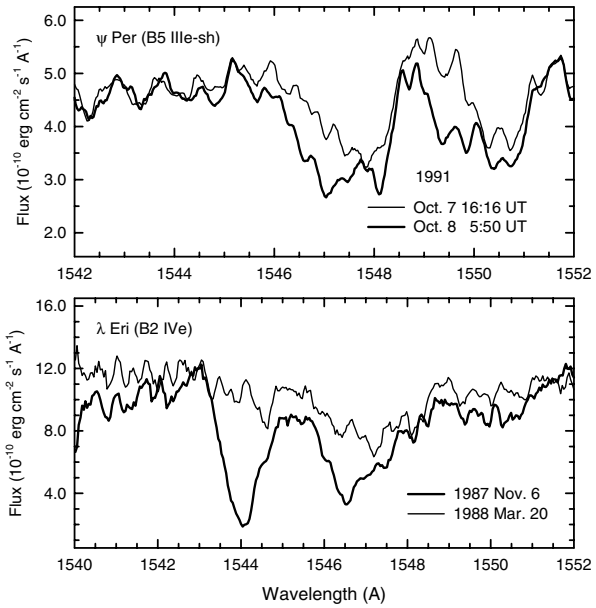

Figure 3. Typical wind variability in Be stars that do not show highly structured winds. Upper panel: a Be star that displays short-term daily cyclic variability. Lower panel: an object in which the wind varies on a time scale of ∼year.

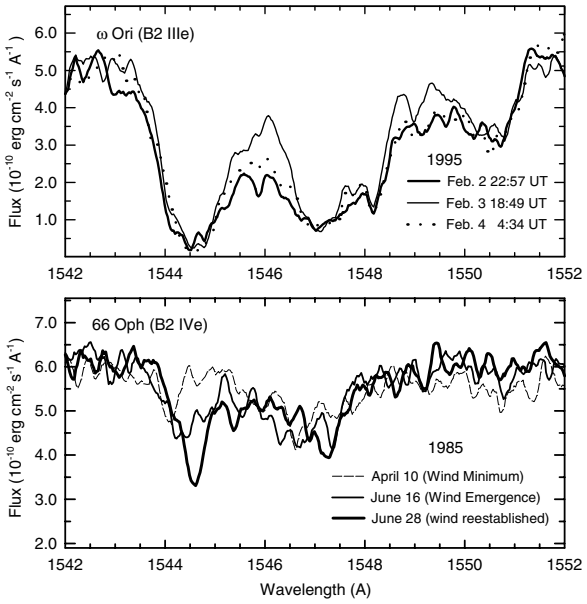

Figure 4. As in figure 3 but for Be stars that display prominent DACs in the wind.

of the wind variability (especially long term) is usually in the DACs that are probably caused by fast-moving localized flows colliding with the exterior wind material. Since short-term variability patterns (red–blue movement) often resemble those observed in O star winds, the DACs may be formed in co-rotating interaction regions. Long-term variability, however, frequently involves DACs moving from blue to red as the wind strengthens.

The photosphere

The current consensus is that the material in the CS disk of a classical Be star originates on the photosphere. Observation of μ Cen, a Be star that has recently been in the process of re-building its CS disk that it lost in the late 1970s, suggests that mass is lost from a localized site of unknown size and the mass loss mechanism must produce a rapid injection of material into the disk. Initially the CS material resides on one hemisphere of the star, but it circularizes into a Keplerian disk in just a few days. Two hypotheses that are currently being discussed are mass loss induced by non-radial pulsations (NRPs) (see NON-RADIAL STELLAR PULSATIONS) and localized magnetic fields.

Since 1980, spectroscopic data of high resolution and S/N from electronic detectors have revealed evidence for NRPs as well as transient micro-emission activity associated with mass ejection from the photosphere. Evidence for NRP comes from observations of weak (∼1–2% $I_{\rm cont}$) absorption components, often called 'bumps', that slowly move from blue to red across the photospheric line profile cyclically, usually with a period less than the star's expected rotation period of ∼1 day. An example of this behavior is shown in figure 5. The photospheric velocity field is given by $V(r,\theta,\phi) = A(1, k\,\partial/\partial\theta, k/\sin\theta\,\partial/\partial\phi)Y_l^m(\theta,\phi)\,e^{i\sigma t}$, where k is the ratio of horizontal to vertical velocity amplitude, Y_l^m is a spherical harmonic function and σ is the NRP frequency in the co-rotating frame. l and m are the pulsation modes. There are m meridians passing through the poles perpendicular to the equator. l is the total number of meridians on the surface and $l - |m|$ is the number of nodes between the poles. Be stars typically show low-order modes with $l = |m|$, or sectorial modes that resemble the sections of an orange. Usually the wave motion is retrograde and beats backwards against the star's rotation with a period of $mP_{\rm obsd}$. For these low-order (g) modes, horizontal motions dominate, as $k \sim \sigma^{-2}$, and the wave crests are hotter than the troughs. The patches on the star containing the crests will contribute more to the integrated line profile than will the trough regions. Consider an $l = 2$ mode in which there are two crests and troughs. The star should be brightest as the absorption 'bump' crosses the center of the line. When the crest is near the stellar limb the star will be fainter and the line should show its greatest distortion. Both effects are observed in many Be stars.

Several types of transient behavior associated with apparently localized mass ejection have been identified in Be stars. These transients are most often observed in the He I lines of Be stars with meager CS disks. Emission flares can abruptly appear and wane in <1 h. Sometimes 2–3 emission components at discrete velocities display ordered variations over the course of a few hours. Weak, central absorption features flanked by weak emission can appear–disappear in <1 h. Transient, high-velocity absorption

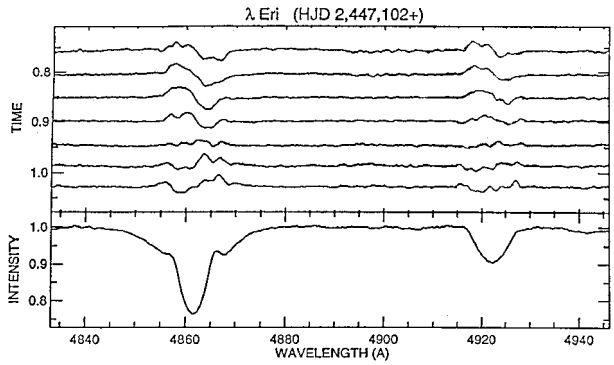

Figure 5. Example of blue–red traveling 'bumps' in photospheric line profiles that suggest the presence of NRPs in a low-order mode. The series of profiles in the upper panel are differences from the mean Hβ and He I λ 4922 profiles displayed in the lower panel. Illustration courtesy of D Gies.

components can appear on the violet side of the line in less than 15 min and fade in 1–2 days. All these short-term phenomena could result from magnetic fields, but so far no magnetic field has been detected in a classical Be star. NRP could be the cause of the transient activity. Some of the most exciting research on Be stars to come will focus on the details of the mass ejection from the photosphere, the process of building the disk and the behavior of the disk as it receives material from a localized site on the star.

Becklin–Neugebauer Object (BN Object)

One of the most powerful infrared sources known, located in the Kleinmann–Low Nebula behind the Orion Nebula, and discovered by Eric Becklin and Gerry Neugebauer in 1967. Its position is RA $05^{h}\ 35.2^{m}$, dec. $-05^{\circ}\,22'$. It is thought to be a very young and massive B star embedded in a dense expanding dust envelope which absorbs the star's visible light and re-emits it in the infrared.

Beijing Astronomical Observatory

The Beijing Astronomical Observatory (BAO) is primarily engaged in astrophysical research. The modern Beijing Observatory was built by the Chinese Academy of Sciences in 1958. Its headquarters are located in Beijing, and there are five observing sites: the Xinglong, Miyun, Huairou, Shahe and Tianjin stations.

Instruments include a 2.16 m (84 in) optical telescope, the largest in the Far East; a multichannel solar magnetic telescope; a meter-wave aperture synthesis radio telescope; and a 1.26 m (50 in) infrared telescope. BAO is also constructing a Large Area Multi-Object Spectroscopic Telescope. In 1991, an observing site in the southern hemisphere was set up in collaboration with the San Juan University of Argentina.

The main research programs include stellar physics, extragalactic studies, solar physics, radioastronomy, an atomic time and frequency service, solar activity prediction, artificial satellite observation and the history of astronomy. A number of discoveries have been made during searches for supernovae, quasars, active galactic nuclei and near-Earth asteroids.

For further information see
http://www.bao.ac.cn/.

Bell, Susan Jocelyn [name following her marriage Burnell, or Bell-Burnell] (1943–)

Radioastronomer, born in York, England. She studied at Glasgow and Cambridge, where in 1967 she was a research student working with ANTHONY HEWISH on a radioastronomy project on interplanetary scintillation. She noticed an unusually regular signal, shown to be bursts of radio energy at a constant interval of just over a second—the first pulsar. Hewish was awarded the Nobel prize for this discovery, circumstances which led to Bell's adoption as a feminist icon. Bell became professor at the Open University.

BeppoSAX (Satellite for X-ray Astronomy)

Italian–Dutch gamma ray and x-ray astronomy satellite launched in April 1996. Named in honour of Italian physicist Giuseppe Occhialini, whose nickname was 'Beppo'. Used for spectroscopic and time variability studies of x-ray sources in the energy band 1–200 keV, including an all-sky monitoring investigation of transients in the 2–30 keV energy range. In 1997, played a major role in identification of gamma ray bursters by pinpointing x-ray emissions from these events, so enabling confirmation of their cosmological distances. The board of administrators of the Italian Space Agency has approved the continuation of BeppoSAX operations until at least 30 April 2002.

Bessel, Friedrich Wilhelm (1784–1846)

Astronomer, geodesist, mathematician, born in Minden, Westphalia, Germany. At the age of 26, became director of Frederick William III of Prussia's new Konigsberg Observatory, where he remained for the rest of his life. Published (1838) the first recognizedly accurate stellar parallax (of 61 Cygni), the earliest accurate method for measuring stellar distances (10 light years for 61 Cygni) (but see WILHELM STRUVE's and THOMAS HENDERSON's claims to priority). Discovered the orbital deflections of Sirius and Procyon due to their then unseen white dwarf companions. These were results of a monumental astrometric program to determine the positions and proper motions of stars—it could be called the beginning of modern astrometry. *Bessel functions*, originally encountered by Daniel Bernoulli, were systematically investigated by Bessel and named for him.

Beta Pictoris

A white-dwarf star of apparent magnitude 3.85, found by the IRAS survey in 1983 to be a very strong emitter of infrared radiation. Following this discovery, extensive studies with large optical telescopes revealed the presence of a disk of dust surrounding the star—possible raw material for the formation of a planetary system. This is particularly interesting as it is a star similar in size to the Sun (1.4 solar diameters), although rather hotter (spectral type A3V). Its luminosity (absolute magnitude 2.4) is about eight times that of the Sun. It is 63 light-years distant, its parallax is 0.052″.

Beta Regio

A prominent upland region of Venus, situated to the north of the planet's equator and centered at 25.3 °N, 77.2 °W. In its greatest dimension it measures 2869 km. It is one of only a handful of Venusian features not to bear a female name. The first features that showed up in early radar surveys of the planet were given the names of letters of the Greek alphabet. When the convention of assigning female names was adopted, a few names that had become well established were allowed to survive. Beta Regio is dominated by three features: two large volcanic calderas, Rhea Mons, and, to its south, Theia Mons, and a prominent rift known as Devana Chasma. This rift passes through both calderas and continues southwards, with a total length of 1616 km. The whole region is considered to be one of the youngest features of the planet, and probably sits atop a local upwelling of the underlying mantle. The lava flows here are some of the most recent on Venus, and it may be that the region is currently volcanically active.

Betelgeuse

The star α Orionis, marking the right shoulder of the Hunter in the ancient constellation figure. It is a red giant of spectral type M2Ib, apparent magnitude 0.45. At a distance of 427 light-years (parallax 0.008″), its apparent brightness arises from its high intrinsic luminosity (absolute magnitude (5.1) which is about 14 000 times that of the Sun. It was the first star to have its diameter reliably determined, by A A Michelson (1852–1931) at the Mount Wilson Observatory, using a 20 foot beam interferometer attached to the 100 inch Hooker reflector. The observed angular diameter of 0.047″ is equivalent to an actual diameter more than double the size of the orbit of Mars. This implies a volume 160 million times that of the Sun, yet its mass is estimated at only 20 solar masses: it is thus a star of exceptionally low density.

Betelgeuse is a semi-regular pulsating variable, its magnitude varying by ± 0.15 over a period averaging about 6.4 years. It is also a radio source and an emitter of strong infrared radiation. Observations by the Infrared Astronomical Satellite (IRAS) indicated that three concentric shells, ejected from the surface of the star in the past, are the sources of the long-wavelength radiation. There are several very faint optical companions.

Bethe, Hans Albrecht (1906–)

Physicist, born in Strasburg, Germany (present-day France), Nobel prizewinner (1967). As professor of physics at Cornell University he worked out the nuclear reactions occurring in the Sun. He worked on the development of the atomic bomb in the Manhatten project, and, after the second World War, pursued again research on stellar nuclear energy sources and the origin of the chemical elements in the alpha-*beta*-gamma theory (Bethe's is the second Greek letter of the theory's name, *see* RALPH ALPHER, GEORGE GAMOW).

Bevis, John (1695–1771)

Doctor and amateur astronomer, born in Old Sarum, Wiltshire, England. Bevis was the only person ever to have telescopically observed (through patchy cloud from Greenwich) the occultation of one planet by another, namely the occultation of Mercury by Venus on 28 May 1737 (the next chance, in theory, is an occultation of Neptune by Mercury in 2067). URBAIN LEVERRIER used Bevis's observations to check his calculations of the motions of the two planets. Bevis erected an observatory in Stoke Newington with which he observed star positions and created a star atlas called *Uranographia Britannica*. It was completed in 1750, but the printer went bankrupt and the printing was never distributed. Less than 20 proof copies survive, and the complementary catalog was never published. Bevis discovered the Crab Nebula, apparently in 1731, and illustrated it on the atlas. Messier had access to a copy of this atlas, referring to it as the *English Atlas* several times, e.g. in the descriptions for the objects M1 (the Crab Nebula, which Messier independently discovered but acknowledging the earlier discovery by Bevis), M11, M13, M22, M31 and M35.

Biela, Wilhelm von (1782–1856)

Austrian army officer, astronomer. Observed in 1826 the periodic comet named after him, and realized that it was identical to the comet seen in 1772 and 1805. The comet broke up in the 1850s and was not seen after the 1852 apparition. Its debris became responsible for the Andromedid (or *Bielid*) shower of meteors seen annually in November in the second half of the nineteenth century, until their orbit shifted out of the annual path of the Earth.

Bielids

A periodic meteor shower that produced November meteor storms after the break-up of Comet 3D/Biela in the 1850s. The shower, also known as the *Andromedids*, had its radiant in the constellation Andromeda. The comet, which had a period of 6.6 years, was last seen in 1852. In 1872, when it should have made a favorable return, there occurred instead a meteor storm peaking at 6000 per hour. The shower returned again in 1885 with a spectacular display touching 75 000 meteors per hour. Weaker activity was seen in 1899 and 1904, after which gravitational perturbations by Jupiter shifted the Bielid stream away from the Earth's orbit. It may return again early in the twenty-second century.

Big Bang Theory

The theory which asserts that the universe originated a finite time ago by expanding from an infinitely compressed state. According to this model, space, time and matter originated together, and the universe has been expanding ever since. Key stages in the history of the Big Bang universe are summarized below.

According to the standard Big Bang model, the very early universe consisted of an extremely high-temperature mixture of radiation (photons) and particles. In accordance with the equivalence of mass and energy inherent in Einstein's special theory of relativity, collisions between high-energy photons would have transformed radiation energy into particles of matter. To be consistent with the conservation laws of particle physics, a collision between sufficiently energetic photons creates a particle–antiparticle pair (e.g. an electron and a positron, or a quark and an antiquark). Conversely, a collision between a particle and its antiparticle results in the annihilation of the particle–antiparticle pair and their conversion into photons.

As the universe expanded and cooled, photon energies quickly declined below the thresholds at which they could continue to create particle–antiparticle pairs. Thereafter, particles and antiparticles rapidly collided and annihilated each other. Baryons and antibaryons (particles such as protons, neutrons and the quarks of which they are composed) underwent mutual annihilation about one millionth of a second after the initial event, when the temperature dropped below 10^{13} K. Less-massive electrons and positrons experienced a similar event a few seconds later, when the temperature had dropped to about 5×10^{9} K. Had there been an exact equality between the numbers of particles and antiparticles, virtually no matter would have remained to form stars and galaxies. Because the destruction of each particle–antiparticle pair produced a pair of photons, and the ratio of photons to baryons in the present-day universe is nearly a billion to one, it follows that the excess of particles over antiparticles in the early universe must also have been about one in a billion.

About 100 seconds after the beginning of time, when the temperature had dropped below 10^{9} K, nuclear reactions combined some of the protons and virtually all the neutrons into nuclei of helium, together with small quantities of other light elements and isotopes such as deuterium, helium-3 and lithium. At the end of this phase there were about 11 hydrogen nuclei (protons) for every helium nucleus. Because helium nuclei are four times heavier than hydrogen nuclei, this corresponds to a ratio, by mass, of hydrogen to helium of about 73:27. The observed relative abundances of the lightest elements very closely matches the predictions of the Big Bang theory.

Thereafter, the expanding universe consisted of a mixture of atomic nuclei, electrons and photons in thermal equilibrium (frequent collisions between photons and particles ensured that matter and radiation shared a common temperature). A few hundred thousand years after the initial event, when the temperature everywhere had declined to a few thousand kelvin, nuclei were able to capture electrons to form complete neutral atoms. This process mopped up the free electrons that had been responsible for scattering photons and, thereby, making space opaque to electromagnetic radiation. The close connection between matter and radiation was broken (this event is called the 'decoupling' of matter and radiation), space became essentially transparent, and the primordial radiation content of the universe was free thereafter to spread ever more thinly through the expanding volume of space. The dilute, redshifted remnant of the primordial radiation is detectable today as the cosmic microwave background radiation.

Some time later, probably within the first billion years after the decoupling, clumps of matter aggregated together to form galaxies, clusters, superclusters and the other large-scale features of the universe. How, when, and in what order these various structures appeared is a matter of debate.

The Big Bang theory is consistent with the observed expansion of the universe (provided that the age of the universe exceeds that of the oldest stars), the relative abundance of the lighter chemical elements, and the existence and properties of the cosmic microwave background radiation. Nevertheless, although certain other issues have been addressed by the 'inflationary' hypothesis, many questions remain unresolved.

Big Bear Solar Observatory

Big Bear Solar Observatory (BBSO) is located at the end of a causeway in a mountain lake more than 2 km above sea level. The site has more than 300 sunny days a year and a natural inversion caused by the lake which makes for very clean images. BBSO is the only university observatory in the US making high-resolution observations of the Sun. Its daily images are posted at http://www.bbso.njit.edu. It specializes in the study of the Sun's magnetic fields and their evolving nature. The BBSO uses daily images to forecast solar magnetic storms which can impact satellites, communication and the power grid. BBSO is operated by New Jersey Institute of Technology.

Binary Stars in Globular Clusters

Globular clusters have long been known to be among the richest stellar groupings within our Galaxy, but for many years they were believed to be largely devoid of the most minimal stellar group: binary stars (see BINARY STARS: OVERVIEW). For many years, the only evidence that any binaries existed in these clusters came from the presence of BLUE STRAGGLERS—stars that appear to be significantly younger than the vast majority of the cluster stars. The nature of blue stragglers remains somewhat unclear, but an early and persistent explanation for their existence is that mass transfer between stars in binary systems prolonged the lifetimes of the mass-gaining stars. Other mechanisms involving single stars can also conceivably explain the existence of blue stragglers, so for many years they offered only weak circumstantial evidence that binary stars reside in globular clusters.

From the early 1950s, when blue stragglers were first discovered, until the late 1980s, more direct evidence for the existence of binaries in globular clusters remained elusive. For example, some of the earliest comprehensive studies of the RADIAL VELOCITIES of the RED GIANT STARS in clusters, in the 1970s, revealed that very few if any of these stars showed the long-term velocity variations expected for SPECTROSCOPIC BINARY STARS. By the mid 1980s it was generally accepted that the binary frequency—the fraction of stars that appear single but that are actually binary stars—of globular clusters was probably under 10%, and certainly much lower than the 50% frequency observed among stars near the Sun.

The lack of binaries in globular clusters seemed consistent with some expectations of that time. Since the stars in globular clusters are closely packed together, they frequently pass quite close to one another. Simple models of the interactions of binaries and single stars in these environments suggested that binaries with initially wide separations (e.g. similar to the Earth–Sun separation or larger) would be disrupted. It was also believed that the low abundance of heavy elements in most globular clusters might somehow inhibit the formation of binary stars.

However, from the standpoint of the stability of globular clusters, the complete lack of binaries became an increasingly perplexing problem. The gravitational interactions of stars within clusters tends to drain energy systematically from the cluster core, leading ultimately to a core collapse to an infinite mass density in a finite time. Since no clusters show convincing evidence of having collapsed in such a dramatic manner, it became clear that something must eventually stop the core collapse process. The easiest way to do so would be to form binary stars in the cluster cores during the late stages of the collapse. The formation of even a few 'hard' binaries—binary stars with very short orbital periods—could entirely halt core collapse in even the most massive clusters. The problem was finding evidence that these binaries actually existed.

When the first X-RAY TELESCOPES were lofted into Earth orbit, one surprising result was the discovery of bright sources seemingly associated with globular clusters. With time, it became clear that these x-ray sources represent short-period binary systems in which mass is transferred from a normal star onto a companion NEUTRON STAR. The frequency of such x-ray binaries is much higher in globular clusters than in the rest of the Galaxy, so they form preferentially in the clusters, perhaps as a result of core collapse. However, many clusters that should have gone through core collapse do not contain x-ray binaries, so other types of binaries must exist in these objects to have halted their collapse.

One of the more unusual types of binaries in globular clusters was discovered with radio telescopes. In 1987, the first PULSAR within a globular cluster (Messier 28, or

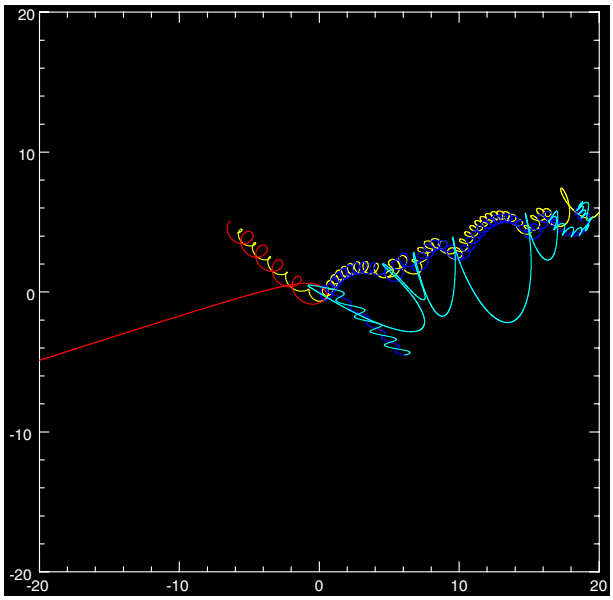

Figure 2. A color plot of the collision of two binary stars in a globular cluster. The lines show the trajectories of the four stars. Initially, two binaries enter the region, one from the upper left (denoted by the red and yellow lines spiraling around one another) and the other from the lower right (as shown by the dark and light blue lines). As the binaries collide, the stars interact strongly. The first effect is that the star denoted by the red line is rapidly ejected into the surrounding cluster as it shoots off the picture to the left. Left behind is a triple system comprised of the stars traced by the yellow, dark blue and light blue lines. However, this triple is not entirely stable as it swaps stars between an inner tight binary system with a more loosely bound star traveling in a larger orbit. In many cases, one of the stars of the triple is eventually lost from the system, leaving one short-period binary and two free stars where there had originally been two intermediate-period binary stars. Such collisions are common in globular clusters, and may provide a way to form contact binaries even in low-density clusters. The details of any given binary–binary collision depend sensitively on the initial configuration of the binaries, so it is still impossible to model any specific interaction within an actual globular cluster. However, the statistical effects of collisions such as the one shown here can be estimated and applied to clusters. (Courtesy E S Phinney and S Sigurdsson.) **This figure is reproduced as Color Plate 5.**

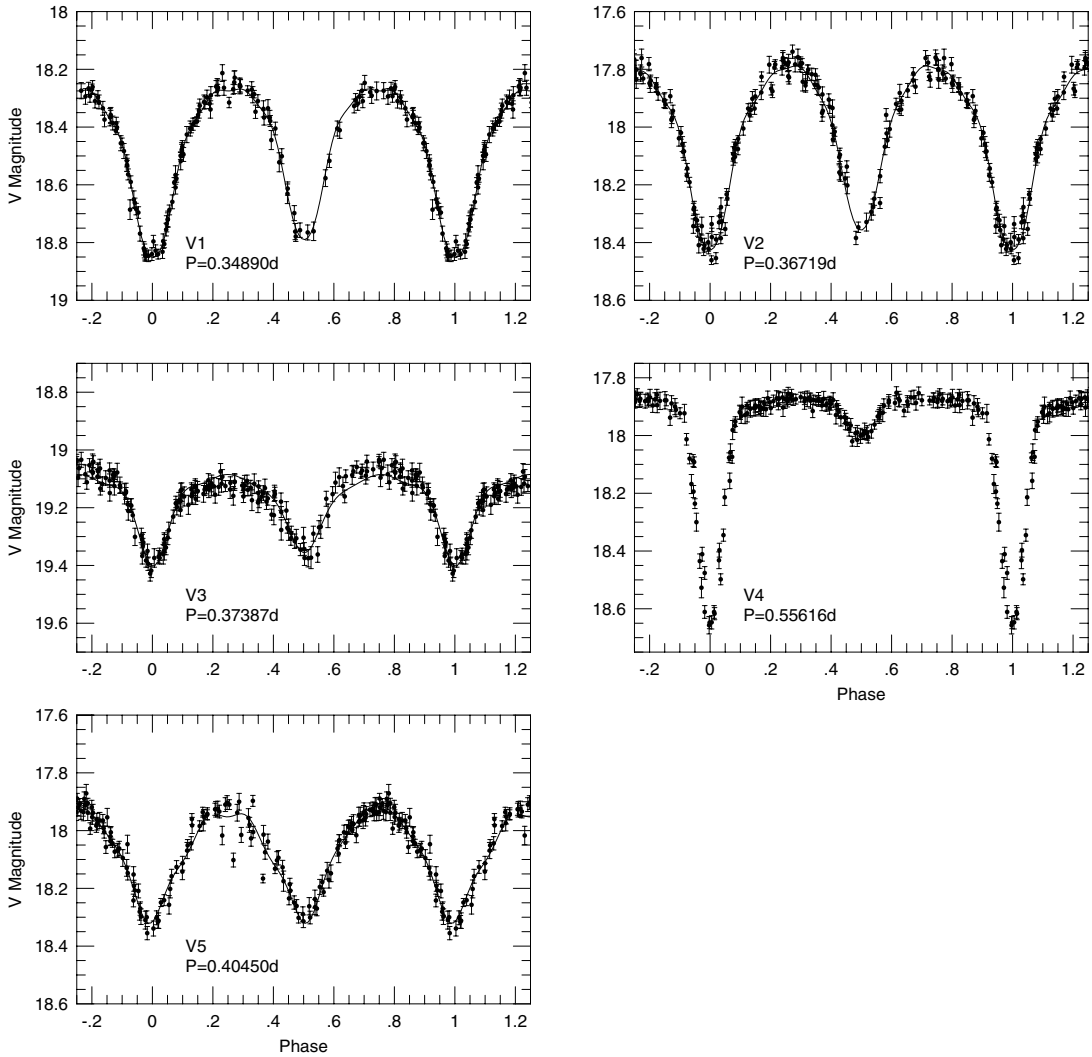

Figure 1. Light curves for five eclipsing binary stars in the globular cluster M 71. Four of these light curves indicate that the binary stars are contact systems in which the two stellar components are in physical contact as they orbit about their center of mass. The star labeled V4 exhibits nearly flat portions in its light curve between the obvious eclipses. This indicates that the binary is a detached system in which the stars are physically separated. All of these binaries have orbital periods of less than one day, while the individual stars are comparable in size to the Sun.

simply M 28) was discovered. These rotating neutron stars exhibit ultra-regular brightness variations on time-scales ranging from 0.002–10 s. Because these natural clocks are so precise, the modulation of their periods can reveal clearly when pulsars are part of a binary system. At least 11 such binary pulsars with normal stellar companions are now known to exist in globular clusters, generally with orbital periods of less than 3 days. The existence of very short pulsation periods of many *single* pulsars found in clusters offers additional indirect evidence of binaries: mass transfer within close binary systems can effectively 'spin up' the pulsars to their observed ultra-fast rotation rates. Subsequent interactions with other single or binary stars in the clusters can disrupt the binaries, leaving the single, short-period pulsar behind. In fact, this seems to be the *only* viable way to produce short-period pulsars in globular clusters. The natural tendency for isolated pulsars to spin more slowly with time would suggest that no short-period pulsars should exist among the ancient stars of a globular clusters.

Some of the first searches in the optical centered on the detection of cataclysmic binaries (CBs) in globular clusters (see CATACLYSMIC BINARIES: CLASSICAL AND RECURRENT NOVAE). CBs are closely related to the bright x-ray sources, except that the compact companion is a WHITE DWARF rather than a neutron star. NOVAE—CBs that undergo particularly violent eruptions on timescales of many years—had been observed near the cores of two globular clusters, but the initial searches for less luminous CBs were frustratingly inconclusive. Only in recent years have ground- and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

space-based observations successfully identified normal CBs in many clusters using optical and x-ray telescopes.

Prior to the discovery of numerous CBs in clusters, examples of more mundane binaries began to reveal themselves in globular clusters. Spectroscopic surveys of red giants started to identify stars that appeared to vary in a way that would be expected for normal binary stars. These spectroscopic binaries have orbital periods ranging from many months to 10 years or longer and demonstrated that relatively wide binaries could survive in many cluster environments. Studies of the changes in the brightness of stars in globular clusters also revealed that some of these are ECLIPSING BINARY STARS. Such systems contain stars in close proximity that, because of the fortuitous alignment of their orbital plane with the Earth, exhibit periodic eclipses as the stars alternately pass in front of one another. Light curves for five such binaries in the metal-rich globular cluster M 71 are shown in figure 1. Both spectroscopic and eclipsing binaries provide indisputable evidence that binary stars do exist in globular clusters. Surprisingly, the numbers of both spectroscopic and eclipsing binaries in clusters imply that, rather than being deficient of binaries, globular clusters may have binary frequencies in the range 25–60%. Such values would be considered nearly normal for stars located in the vicinity of the Sun.

The most recent surveys of many clusters have largely confirmed this result. Indeed, no clusters studied sufficiently carefully have failed to reveal either spectroscopic or eclipsing binaries or blue stragglers. Though the latter may form via stellar collisions or as a result of complex interactions between wide binary stars, these observations have strongly confirmed that binary stars are *not* rare in globular clusters, simply hard to find!

Blue stragglers re-entered the subject of cluster binary stars as it became clear that 5–10% of these stars are eclipsing systems. Many of these binary blue stragglers turn out to be contact binaries, systems in which the two orbiting stars are in physical contact. Because the stars significantly distort each other, they are not spherical in shape and are always either entering or leaving eclipse; thus, their light curves are never constant (four of the five stars whose light curves are shown in figure 1 are contact binaries). The components of such contact binaries cannot avoid a future fate in which the two stars coalesce into a single, more massive star. The resulting merged object would become a blue straggler. Especially in the lower-density globular clusters, this appears to be the most likely way to form blue stragglers (though see below for another possible mechanism that may operate in low-density clusters).

Now that binary stars are routinely detected in globular clusters, new questions have been raised. For example, is the mixture of binary star types and orbital periods similar to that observed near the Sun? Certainly, clusters contain far more x-ray binaries and a large proportion of short-period binary pulsars than among field stars throughout the Galaxy. It is also clear that the longest-period binaries in clusters are preferentially destroyed. Short-period systems can be created preferentially in dense clusters, either through star–star captures (this is rare except in the densest environments) or via 'collisions' of wide binaries (more common; see figure 2 for an example of what this may look like). Different clusters appear to affect their binary star populations in different ways, but we lack a good understanding of why this is the case or even if the binary star populations depend on global globular cluster properties such as total mass, or chemical abundance. The origin(s) of cluster binaries is still also under debate. There is clear evidence that some binaries are 'primordial'—that is, they were formed when the cluster itself was formed. But dynamical processes in some clusters—particularly the densest clusters—clearly can form binaries via a variety of mechanisms that have only begun to be explored in detail.

Binary Stars in Planetary Nebulae

The classical view of PLANETARY NEBULAE (PNe) is that they are ejected from all single stars of low to intermediate mass at the end of the asymptotic-giant-branch stage. However, observations made over the past two decades have made it increasingly clear that binary stars actually play a significant, and possibly dominant, role in the PN ejection process.

Common envelopes and UU Sagittae

Two key events in this subject occurred almost simultaneously in the mid-1970s, and provide a beautiful example of the interplay of theory and observation in astrophysics.

One of these events was an apparent theoretical resolution of the puzzle of the origin of extremely close binaries containing WHITE-DWARF (WD) components. These systems include the short-period cataclysmic binaries and close but detached 'pre-cataclysmic' main-sequence–WD pairs such as V471 Tauri (an eclipsing binary in the Hyades cluster, containing a hot WD and a K-type main-sequence companion, with an orbital period of only 12.5 h). WDs are the cores of RED GIANT STARS, yet for these extremely close binaries the entire system is much smaller than the red-giant progenitor of the WD. It was realized that, in fact, the companion main-sequence star must recently have been *inside* the red giant. This insight led to the concept of 'common-envelope' (CE) interactions during the evolution of binary stars.

The CE scenario starts with a binary that is wide enough for the more massive component to grow to red-giant dimensions before any interaction with its companion occurs. Only then does the red giant swallow its companion, which encounters frictional drag as it orbits within the low-density envelope of the red giant. The orbit spirals down, transferring its energy to the CE. Eventually, the CE is ejected, leaving a much closer binary containing the main-sequence star and the remnant core of the red giant. The core then evolves to high surface temperature, pouring out ultraviolet radiation that ionizes the ejected envelope and making it visible as a PN. Next, after the PN has dissipated into space, the core enters the WD cooling sequence, producing a V471-Tau-like binary. Eventually, as the orbit contracts owing to gravitational radiation or other mechanisms, the main-sequence star will start transferring mass to the WD, transforming the system into a cataclysmic or nova-like variable. It is now generally believed that the CE mechanism is the dominant way in which cataclysmic binaries are made. Moreover, the system may eventually undergo a *second* CE interaction, when the main-sequence star attempts to become a red giant itself, leading to a very close, double WD binary. Such systems may be the progenitors of type Ia supernovae.

This theoretical scenario predicts the existence of very close binaries inside PNe, which indeed would be the 'smoking gun' showing that the CE interaction actually does occur in the real universe. The second important event in the 1970s was the discovery of a close-binary PN nucleus (PNN), found in the same year that the first theoretical papers predicting its existence were published. This was UU Sagittae, the central star of the planetary nebula Abell 63. It is an eclipsing binary, first identified in 1932, although the realization that it is the nucleus of a faint PN did not occur until 1975. The orbital period was found in 1976 to be an astonishingly short 11.2 h, implying that the hot nucleus orbits only about one stellar diameter away from its main-sequence companion.

Known close-binary nuclei

The discovery of UU Sge sparked systematic surveys of PNNi in order to search for binarity. Most of the searches have been done photometrically, i.e. by seeking periodic light variations of the central stars. Four PNNi—UU Sge, V477 Lyr, BE UMa, and the nucleus of SuWt 2—have been found to be eclipsing binaries, with periods of about half a day up to 2.4 days. Eight additional systems do not eclipse, but are still variable in light because of the strong heating effects that arise on one hemisphere of a cool main-sequence star that orbits closely around an extremely hot companion. The orbital periods of these systems range from a remarkable 2.7 h (one of the shortest periods known for a detached binary) to 2.9 days. In addition, the central star of NGC 2346 is a 16 day spectroscopic binary, and there are three known 'Abell 35-type' PNNi whose composite spectra clearly show that two stars—a hot nucleus, and a cool, rapidly rotating companion—must be present.

These known binary PNNi constitute roughly 10% of randomly selected central stars. If we take into account the fact that the main discovery technique for these binaries—photometric variability—is ineffective for binaries with periods of more than several days (since then the heating effects do not occur), we see that the true fraction of binaries among PN central stars could be much higher, if there is a significant population of binaries with longer periods.

Morphologies of nebulae with binary nuclei

It is generally found that PNe known to have been ejected from close binaries are axisymmetric, showing either elliptical or more pronounced butterfly or bipolar shapes. These non-spherical morphologies appear consistent with the CE scenario, if one imagines that the CE interaction will eject matter predominantly into the orbital plane of the binary. Later on, when the hot component of the nucleus develops a fast, spherical, low-density wind (typical of all hot stars), the wind will attempt to plow out into the slower-moving ejected envelope. Along the polar directions, the wind will break out first, producing balloon-shaped bubbles; however, in the orbital plane, where the previously ejected envelope is much denser, the fast wind will be decelerated in a 'snowplow' fashion.

There is space here only for a few images of PNe known to have binary nuclei. Figure 1 shows a ground-based image of Abell 41. It indeed has the general morphology predicted above: the blobs on either side of

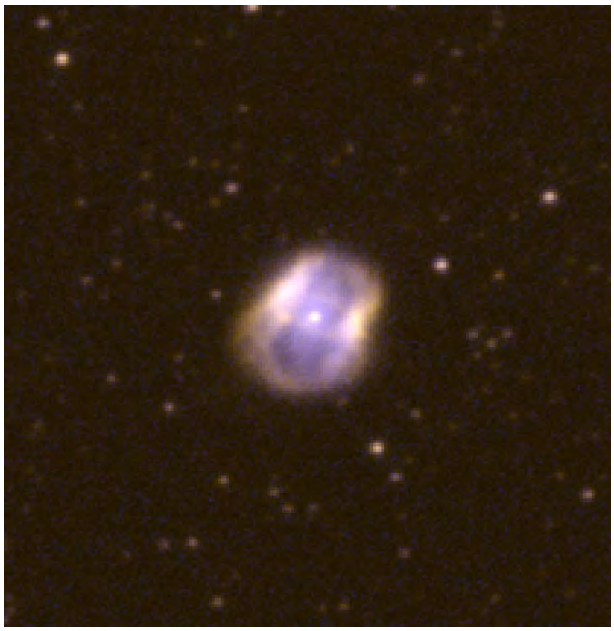

Figure 1. Ground-based CCD image of Abell 41, a planetary nebula whose central star is an extremely close binary with a period of 2.7 h. The image is the sum of [O III] and Hα, obtained with the Cerro Tololo 0.9 m telescope. Note the axisymmetric structure, with blobs marking the orbital plane of the binary, and wind-blown balloons at the poles.

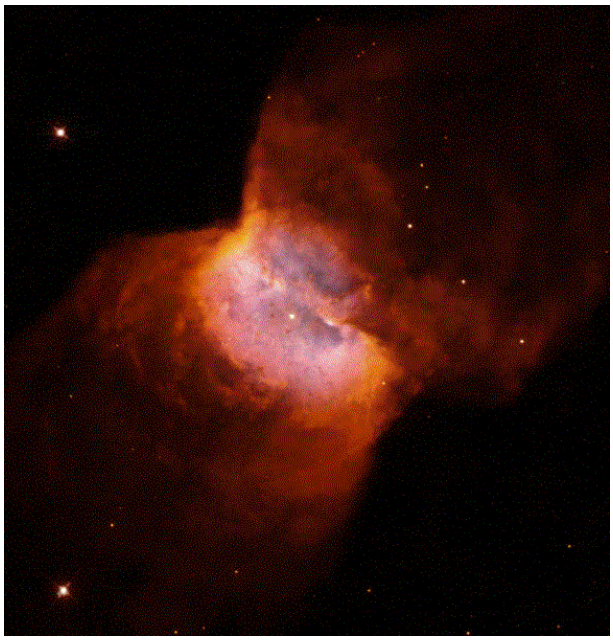

Figure 2. Hubble Space Telescope image of NGC 2346, whose nucleus is a 16 day binary. This is a classical 'butterfly'-shaped planetary nebula, with a dense equatorial ring and wind-blown bubbles perpendicular to the orbital plane. *NASA/STScI Hubble Heritage image.*

the central star mark the orbital plane of the binary, where the gas density of the ejected CE is high and the subsequent fast wind has been unable to escape. Perpendicular to the orbital plane, however, the fast wind has succeeded in inflating two 'bubbles', because the density of the ejected envelope is much lower there.

Figure 2 shows an extreme case of a 'butterfly' PN, NGC 2346, obtained with the HUBBLE SPACE TELESCOPE. Here again the binary PNN is surrounded by a dense ring, ejected as a consequence of the CE interaction; note the pinched waist around the central star. The fast wind has broken out perpendicularly to the orbital plane, producing the spectacular bipolar shape.

In some cases, only the equatorial ring is seen. Figure 3 is an example, showing an almost edge-on ring around the central star of SuWt 2, a 2.45 day eclipsing binary. This 'wedding-ring' PN has an extremely high 'density contrast' between its equatorial and polar regions. In fact, if one is in a poetic mood, one can think of the wedding ring as symbolizing the mystical union of the two stars. . .until one realizes that cataclysmic events and an eventual blow-up loom in the future for this couple.

Are most planetary nebulae ejected from binaries?

As described above, PNe known to contain close-binary nuclei are virtually all axisymmetric, with varying degrees of density contrasts between orbital plane and poles. It is at present an unsolved question whether the opposite is true, i.e. whether *all* non-spherical PNe are ejected from binaries. This is a crucial issue, since the large majority of PNe are in fact observed to be highly non-spherical, leading to the suggestion that most PNe are ejected from binary stars. There may be other mechanisms (e.g. rotation of the red-giant progenitor, magnetic fields, pulsation, convection) that could produce a non-spherical ejection from a single, spherical star. However, on closer examination, the presence of a reservoir of angular momentum generally seems to be required (for example, to spin up the star to sufficient rotational velocity to make the PN ejection non-spherical or to generate a sufficient magnetic field to influence the ejection magnetically), and a companion object is the most obvious such reservoir.

Moreover, it may be that a companion of only modest mass (such as a brown dwarf or even a massive planet) may be sufficient to cause a non-spherical PN ejection, either through the CE interaction or through tidal forces without needing the actual stellar cannibalism.

If we combine the above considerations with the already high fraction of directly detected binary central stars, which were found using an observational technique that is only sensitive to the shorter-period binaries, we are tempted to conclude that binary interactions have a major, and possibly dominant, influence on the ejection and shaping of planetary nebulae.

This conclusion, however, has not yet been tested with direct observations (e.g. a large-scale search for radial-velocity variations on timescales of weeks to months). At present we are left with the words of the poet Robert FROST:

Figure 3. Ground-based [O III]+Hα image of SuWt 2, obtained with the Cerro Tololo 0.9 m telescope. This PN appears to be a ring with a very low ratio of height to radius. It is viewed close to edge on, and the central star is an eclipsing binary, showing that the ring was ejected into the orbital plane.

We dance 'round in a ring and suppose,
But the Secret sits in the middle and knows.

Binary Stars: Detached

Detached binaries are binary star systems where both stars are smaller than their ROCHE LOBES. These systems are useful in determining the basic properties of stars such as mass and radius since in most cases there has been no large-scale mass transfer between the two stars.

Basic stellar data

If a detached system is a double-lined spectroscopic binary with the orbit oriented nearly edge-on so that eclipses occur, then the fundamental properties of the two stars can be determined through careful analysis of the radial velocities and light curve in one or more photometric passbands (see also ECLIPSING BINARY STARS). Although it is possible in principle to measure the mass of a single star via the gravitational REDSHIFT, the effect in non-degenerate stars is so small as to be immeasurable. Thus practically all of our knowledge of stellar masses has come from studies of binary stars, and particularly detached binaries for stars of solar mass and above.

The radius of a single star can be measured directly using interferometric techniques, but to date this has only been possible for a handful of nearby supergiants such as BETELGEUSE. If the distance to a star is known, then the radius (R) can also be determined indirectly with the Boltzmann equation since the luminosity (L) can be estimated:

$$L = 4\pi R^2 \sigma T^4$$

where the effective temperature (T) of the star is determined from the spectrum and σ is the Stefan–Boltzmann constant. This method is limited by its requirement for an accurate distance to the star and by the numerous assumptions and calibrations involved. Therefore the majority of our knowledge about stellar radii has come from the analysis of observations of binary stars. Detached binaries whose components are much smaller than their Roche lobes are good approximations to single stars because there is little physical interaction between the stars and they are not subject to the evolutionary complications arising from mass transfer as in the semidetached systems like ALGOL.

Double-lined spectroscopic binaries that eclipse provide masses and radii directly. The spectroscopic data provide the mass information, although in the absence of eclipses the information is incomplete. Because the orbital inclination and the semi-major axis of the orbit are perfectly correlated, only the minimum masses can be determined. If the system has eclipses, the inclination can be determined and thus the masses can be directly measured.

Data compilations

Popper (1980) compiled the then available data on the masses, luminosities and radii of stars based on observations of mostly detached systems. Popper noted the paucity of data on stars of spectral type B5 and earlier. Hilditch and Bell (1987) published data on 31 such systems with 16 of them being detached binaries. Harmanec (1988) collected observations published since 1980 and also provided approximation formulae for the basic stellar parameters based on the observations.

Binary Stars: Overview

Binary stars are pairs of stars in a gravitationally bound, periodic orbit around their common center of mass. Half or more of all stars are parts of binary systems, and this can reach 90% where the census is very complete. In most cases, the two stars of a binary formed together, out of a single gas cloud, and so have the same age and the same initial chemical composition. A few systems arise from gravitational capture processes between previously single stars or via star exchange between a pair and a single star or two pairs, most often in environments like the centers of GLOBULAR CLUSTERS, where stars are very close together.

Binary stars are of interest and importance for several reasons. They provide the only accurate measurements of stellar masses, and the mass of a star turns out to be the primary determinant of its life cycle (see STELLAR EVOLUTION). Second, a variety of astronomical processes and phenomena occur only in binary systems, especially ones where the stars interact at some time in their lives (called close binaries; the opposite is 'wide'). Third, possible orbits for stable, habitable planets around a star are greatly restricted when the star is part of a binary (see THREE-BODY PROBLEM). About one binary in five is gravitationally bound to one or more additional stars in a MULTIPLE STAR system. Generally, the third and additional stars are far enough from a close binary that they do not affect its evolution very much.

Classification

Binary systems can be classified in terms of (a) how they were discovered and studied, (b) their current physical state or (c) their status within an evolutionary scenario. A given system can normally be classified in all three ways.

Classification by method of discovery

The classes by methods of discovery or study are:

(a) Common proper motion (CPM) pairs (where the stars are seen as separate dots of light and move across the sky together, but the orbit period is too long for orbital motion to have been seen).
(b) VISUAL BINARIES (where two dots of light are resolved and seen to orbit each other).
(c) Astrometric binaries (where a single image is seen, but it is elongated and the orientation changes with the orbit period, or a single image moves periodically in the sky).
(d) Spectrum binaries (where the spectrogram of a single image shows two sets of lines characteristic of two stars of different spectral types).
(e) SPECTROSCOPIC BINARIES (SBs, where the spectrogram of a single image shows one or two sets of lines whose radial velocity varies periodically; these are called single-lined and double-lined SBs respectively).
(f) ECLIPSING BINARIES (where one star passes in front of the other from our vantage point, so that the total light we see coming from the system is temporarily dimmed; where the two stars are very close together, gravitational distortions of their shapes or illumination of one by the other can mimic eclipses; these are called ellipsoidal binaries).

Many systems can be studied by more than one of these methods. ALGOL, for instance, is both a spectroscopic and an eclipsing binary with a period of about 3 days, while 70 Ophiuchi is both a visual and a spectroscopic binary, with a period of 88 years.

On average, eclipsing and spectroscopic binaries will have the shortest orbit periods and the smallest orbit sizes (semi-major axes), while visual binaries and CPM pairs have the longest periods and widest separations between the components. The ranges (when both stars are normal main sequence stars) is from several hours up to several million years in period and from twice the radius of the Sun up to about 0.1 PARSEC in separation. Binaries with WHITE DWARF, NEUTRON STAR or BLACK HOLE components can have still shorter periods, down to a few minutes, though the systems will be short-lived. Widely separated pairs, where the stars never interact or influence each other's evolution are also called DOUBLE STARS.

Two objects of masses M_1 and M_2, bound together by gravity can be described by a modification of KEPLER'S THIRD LAW of motion, which says

$$(M_1 + M_2)\,P^2 = a^3$$

where M_1 and M_2 are measured in solar masses ($1M_\odot = 2\times10^{30}$ kg), P is the orbit period in years, and a is the semi-major axis of the relative orbit in ASTRONOMICAL UNITS. Thus, we can find the sum of the masses for any pair where P and a are measurable, and the individual masses as well whenever the ratio can be obtained from the ratio of the stars' distances from their common center of mass, or the ratio of their speeds around it.

Classification by current physical state

Binaries are also classified in terms of the masses and evolutionary states of the two stars and the extent to which each fills its Roche lobe (see figure 1). Detached systems are ones where neither star fills its lobe; semi-detached systems have one lobe-filling star (often a RED GIANT), and material spilling through the point L_1 onto the other star or into a disk orbiting around it. In contact binaries, both stars fill their Roche lobes (also called the inner Lagrangian surface). If material has overflowed the lobes and surrounds both stars, we speak of a common

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

envelope binary. Gas that reaches the point L_2 is free to leave the system completely, often carrying large ANGULAR MOMENTUM with it, so that the stars spiral together. Material can be transferred from one star to the other even in a detached system if one has a strong stellar wind.

These classes are somewhat correlated with those of the previous subsection. A contact system, for instance, will almost certainly be seen to eclipse, while a detached system with two main sequence stars is unlikely to, and a detached system with two white dwarfs almost certainly will not.

Binary systems can include stars of all possible masses from 0.085 to 100 or more solar masses and stars at all evolutionary stages, from PRE-MAIN-SEQUENCE STARS, through the main sequence, red giants and supergiants, and later phases, up to white dwarfs, neutron stars and black holes. Not all combinations are, however, possible. For instance a $30M_\odot$ star will have completed its main sequence lifetime before a $1M_\odot$ star has begun core hydrogen burning, so you will never see a pair consisting of $30 + 1M_\odot$ with both stars on the main sequence. Pairs where both stars are in the same, short-lived evolutionary phase (like binary Cepheid variables) are naturally rather rare.

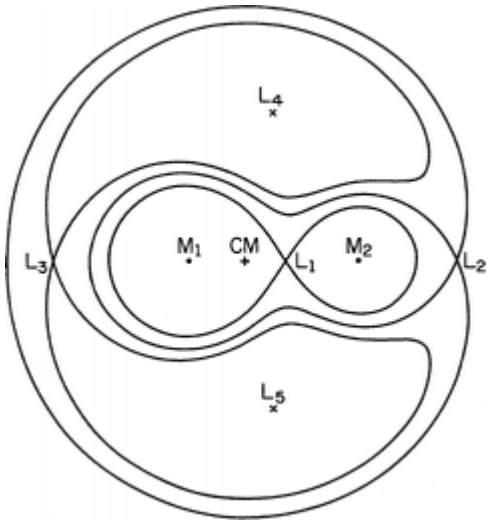

Figure 1. The Roche geometry, showing equipotential surfaces in a coordinate system that rotates with the orbiting star pair. When neither M_1 nor M_2 fills the innermost contour shown (Roche lobe), the system is non-interacting. When one star has evolved and expanded enough to fill its Roche lobe, material flows through L_1 (the first Lagrangian point) onto the other star. When both lobes are filled, the contact system is likely to merge. Common envelope binaries over-fill both lobes, and material that reaches are far out as L_2 can leave the system, typically carrying more then its fair share of angular momentum. (From Webbink R F 1991 *The Astronomy and Astrophysics Encyclopedia* ed S P Maran (New York: van Nostrand) p 81.)

Classification by evolutionary phase.
Assigning binary systems to their place in a scenario for how systems evolve is the most uncertain of the methods, but also the one that provides the most physical understanding. These classes are often named for a prototype, for instance Beta Lyrae stars (in which mass transfer from the more massive, lobe-filling star to its companion has just started and is happening rapidly), Algol variables (in which material is being transferred more slowly from a depleted red giant to its now more-massive companion) and V 471 Tauri stars (detached pairs of white dwarf + red dwarf, expected to evolve into cataclysmic variables).

Quite often, the prototype is not very typical of its class. This is not really surprising. The first example of a class to be found is likely to be unusually bright or otherwise conspicuous. Algol, for instance, is part of a triple system; and V 471 Tauri probably has a bit of mass transfer going on (so it is bright for its type). At least 50 classes of this sort have been named in the astronomical literature, but many would be recognized only by a few specialists.

History

Relatively close star pairs, resolvable with the naked eye like Castor and Pollux, were known to the ancients. Most of these are optical doubles, that is, stars at different distances from us, seen by chance in about the same direction, and not physically bound together. With the advent of the telescope, pairs closer than the naked eye separation limit (about 30") began turning up, starting with Mizar (the middle star in the handle of the Big Dipper) observed by the Italian astronomer Benedetto Castelli in 1617.

William Herschel (see HERSCHEL FAMILY) began systematic cataloguing of double stars in about 1775 and identified about 700 over the next decade. The 1827 catalog of WILHELM STRUVE include 3110 pairs. Most astronomers of the time thought that all these were optical doubles because they believed that all stars had about the same intrinsic brightness and, therefore, that a pair with very different apparent brightnesses must be at different distances. The English polymath, John Michell, had, as early as 1767, suggested on statistical grounds that many of them must be physically bound pairs, because there were too many to be just change alignments.

This hypothesis was confirmed in 1804 by William Herschel, who had been attempting to use the 5" pair Castor A and B to get the PARALLAX of the brighter, and so presumably closer, star. He found, instead, orbital motion and described himself as like Saul, who went out to seek his father's asses and found a kingdom. That the orbits are elliptical, as required by Newtonian gravity, was established for Xi Ursae Majoris by Felix Savary in 1827 (figure 2).

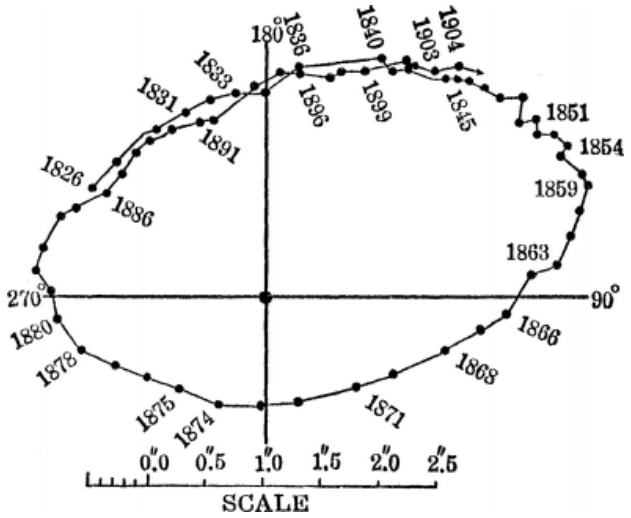

Figure 2. The orbit of Xi Ursae Majoris, the first system for which ellipticity of the orbit was established, by F Savary in 1827. The stars are now back in the same relative position as they had in about 1880. (From Russell H N, Dugan R S and Stewart J Q 1926 *Astronomy* (Boston: Ginn) p 682.)

Herschel's son John continued the cataloguing of double stars, bringing the total to more than 10 000. The modern inventory exceeds 100 000, but only about 1000 of these have had their orbits fully observed, and the number with accurate enough orbital elements for the measured masses to be useful is only a few hundred. It is necessary to know the distance to a visual system as well as the orbit parameters to get meaningful masses.

The first astrometric binaries were Sirius and Procyon, whose sinusoidal motion through the sky was traced out by Friedrich Wilhelm Bessel in the decade leading up to 1844. He described them as having invisible companions of roughly their own mass. They became visual binaries with the discovery of their faint (white dwarf) companions by Alvan G Clark in 1862 and Schaeberle in 1895. Many other astrometric binaries have since been promoted to visual systems, when improved observing techniques have allowed the resolution of smaller separations and fainter stars, often by methods of OPTICAL INTERFEROMETRY.

Algol is the eye of Medusa in the constellation Perseus, and the name means 'the ghoul' or 'the demon'. This suggests that its variable brightness was known to the medieval Arab astronomers who assigned the name. But the first documented report of its occasional fadings came from Montanari in 1669. John Goodricke established in 1783 that the variation is periodic, with the star declining to about one-third of its normal brightness and recovering during about 10 h out of its 68 h period. He suggested the cause might be dark spots on a rotating surface (like SUNSPOTS, but much bigger and darker) or partial eclipse of the star by another body. At the time only eclipses of the Sun, Moon and satellites of Jupiter had been seen, and the idea did not catch on.

The first spectroscopic binary was, again, Mizar (the brighter component of the pair resolved by Castelli). Antonia C Maury of Harvard College Observatory recognized that one of its absorption lines, the K feature of ionized calcium, was sometimes split into two components, with variable separation. This was announced in 1889 by the observatory director, William C Pickering, who correctly interpreted the changing wavelengths of the line as a Doppler shift due to the velocities of two stars of about the same brightness and temperature orbiting each other with a period of 665 days.

H C Vogel, in the same year, reported periodic wavelength shifts in the spectrum of Algol, showing it to be a single-lined spectroscopic binary. The cooler, red giant star that causes the eclipses is faint enough that the techniques of the time could not detect its absorption lines in the combined spectrum. In light of these results for Mizar and Algol, the existence of eclipsing binaries was quickly also recognized by the astronomical community.

Well over 1000 spectroscopic binaries (the majority SB1s, though this is partly a matter of how hard you work) have been studied at some level. Because the Doppler shifts we see are projections of the real orbital velocity along our line of sight, the orientation of the system must be known in order to get the stellar masses. Eclipsing systems are, of necessity, seen nearly edge-on, and the details of their light curves reveal the precise orientation. Thus binaries seen as both spectroscopic (SB2) and eclipsing systems are our main source of masses for systems that are too far away from us to be resolved as visual binaries and to have accurate distance determinations.

Progress in understanding the evolution of binary systems necessarily awaited an adequate theory of stellar evolution for single stars. This was achieved in the decade following 1939, when it became generally recognized that red giants represent an evolved phase, in which fuel for hydrogen fusion has been exhausted at the center of the star. The main sequence lifetime of a star then has to be proportional to its fuel supply (mass) divided by its consumption rate (luminosity), leading to an approximate relation, lifetime = 10^{10} yr $(M/M_{\odot})^{-2.5}$ (because massive stars are much brighter than little ones). From this soon arose the so-called Algol paradox.

Codified by Otto Struve in 1953, the paradox consisted in the fact that we see large numbers of binary systems, mostly eclipsing ones, like Algol, in which the more evolved (red giant) star is the less massive one. The seeds of a solution were already present in a 1941 paper by Gerard P Kuiper, in which he pointed out the possibility for mass transfer between stars inherent in the Roche geometry. John Crawford, in 1955, suggested that such transfer could result in reversing the initial mass ratio of a close binary, so that the original secondary

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

could become the more massive star while it was still on the main sequence and receiving contributions from the original primary, evolved to a red giant configuration. More quantitative study appeared in the 1960 PhD dissertation of Donald C Morton, followed by a flowering of relevant work in three groups centered around Miroslav Plaveç (Prague), Rudolph Kippenhahn (Munich) and Bohdan Paczyński (Warsaw).

More recently, mass transfer in close binaries has been used to account for a wide variety of other unexpected combinations of properties, including BLUE STRAGGLERS, barium stars without technetium and gamma-ray bursters.

Binary statistics

Numbers, especially stellar masses, derived from study of individual binary systems help to guide our theories of stellar structure and evolution. In contrast, statistical information on binary populations can provide light on the processes of STAR FORMATION and the evolution of the binary systems themselves.

Gerard Kuiper, the first to publish on statistical issues in 1935, had data on a few dozen visual binaries and CPM pairs and a double handful of spectroscopic, eclipsing systems, with a large gap in orbit period (or semi-major axis) between the two groups. He nevertheless bravely drew a dotted line between the two peaks and suggested that the real distribution in period or separation was fairly flat, meaning roughly equal numbers of systems per logarithmic interval, over the entire possible range, from the sum of the radii of the two stars to about 0.1 pc, beyond which the stars will be pulled apart by the tidal force of the galaxy and of other passing stars. Subsequent work has, in general, validated his monumental extrapolation (figure 3).

Astrometric binaries and optical interferometry have done a great deal to bridge Kuiper's period gap. Not surprisingly, the harder you look, the more companions you find, both very faint ones and ones at awkward separations. The period distribution in modern data is very broad, with a gentle peak at a few years, and wings extending to a few hours on one side and a few million years on the other. Naturally, small separations and periods disappear when the primary becomes a red giant, and large separations and long orbit periods cannot survive in dense clusters of stars.

Kuiper also looked at the distribution of binary mass ratios, $N(M_2/M_1)$, in the hope of deciding how the systems formed. He expected that formation by the fission of a single, rotating cloud would lead to components of nearly equal mass (M_2/M_1 close to 1), while separate formation followed by capture would lead to the average primary having a companion a good deal less massive than itself, since low-mass stars are much commoner than high-mass stars. He focused primarily on single-lined spectroscopic binaries, on the grounds that SB2s and visual systems could be detected only when the stars were of nearly equal luminosity, hence nearly equal mass, and so were biased samples. He found a distribution $N(M_2/M_1)$ that indeed rose toward small values. But his sample was clearly biased in the opposite sense, against systems with mass ratio near unity.

Modern data say that the mass distribution for primaries of close binaries that have not yet experienced any mass transfer is essentially the normal initial mass function (IMF). The situation is less clear for the secondaries, there being still no large truly unbiased samples. Some samples show $N(M_2/M_1)$ rising monotonically to the smallest values to which the data are complete; others show a second peak near $M_2/M_1 = 1$. In any case the processes that might compete to form close binaries now include several additional mechanisms (fragmentation, hierarchical clustering, photodisintegration etc). Thus the functional form of the mass ratio distribution is no longer a clean test between two possible scenarios.

Are the distributions of binary period and mass ratio different in different STELLAR POPULATIONS, and is the total fraction of binaries among the stars also variable? Probably, but our data are very limited. The faint, low-mass systems that make up most of the local sample are difficult to study at large distances and in crowded regions of the sky. It was thought at one time that there

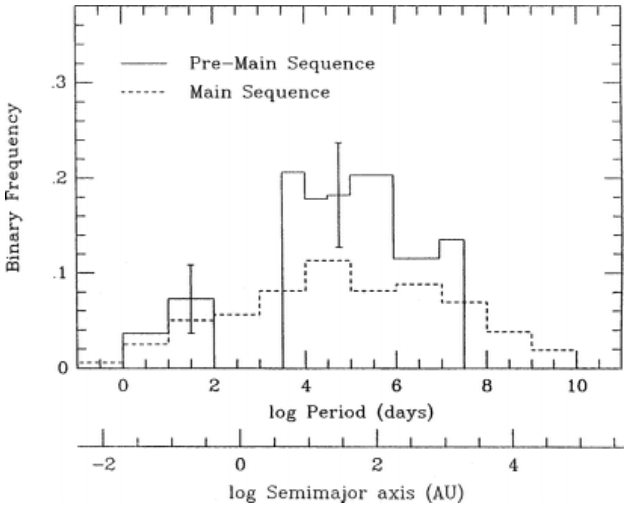

Figure 3. Distributions of semi-major axes and periods for solar-type main-sequence binaries (broken line) and pre-main sequence systems (full line—the regimes of log P = 2–3.5 and greater than 7.5 have not yet been properly surveyed). The distributions are very broad, ranging from less than a day (contact systems) to millions of years (systems at risk of tidal disruption), and peak at periods of several years to decades and separations of 10–100 astronomical units, the regime best explored with speckle interferometry and not available to Kuiper. (From Mathieu R D 1994 *Ann. Rev. Astron. Astrophysics* **32** 469.)

were almost no binaries among the old, POPULATION II stars that make up the halo and globular clusters of our Milky Way. This was due to two kinds of selection effects. First, short-lived systems are long since gone, and, second, longer-lived ones are exceedingly difficult to detect. With modern photometry, one finds that the incidence of, for instance, W Ursae Majoris (low-mass, contact) binaries is about the same in many globular clusters as it is in the solar neighborhood, one for every couple of hundred main sequence stars.

Statistics of evolved systems test our understanding of the processes of mass and angular momentum transfer and loss from the systems and the lifetimes of the survivors. Interesting issues include (a) the cause of the gap in the distribution of periods of cataclysmic variables between the 2 and 3 h, (b) the relative frequency of single and binary WOLF–RAYET STARS, (c) the numbers of binary and millisecond PULSARS relative to the number of low-mass X-RAY BINARIES that are supposed to be their ancestors, and (d) the numbers of x-ray binaries with black hole versus neutron star primaries.

The vast majority of both visual and spectroscopic eclipsing binaries with well-determined orbits contain very ordinary kinds of stars, mostly main sequence and slightly evolved ones with masses between about 0.5 and $5M_{\odot}$. We badly need:

(a) Good masses for very faint (low-mass) stars of both high and low metallicity, to trace out the boundary between true stars and brown dwarfs.

(b) More data on stars of more than about $30M_{\odot}$ to find out the maximum possible mass for a stable star under various conditions and how fast mass is lost early in the life of the star.

(c) Good orbits for systems containing stars in short-lived, but interesting, evolutionary phases, like LUMINOUS BLUE VARIABLES, Wolf–Rayet stars, Cepheid variables, RR LYRAE STARS, blue stragglers and many others.

Even then, serious thought and detailed modeling will be required, because in many cases we cannot be sure that the examples in binaries with periods short enough to be well observed are physically the same as seemingly similar stars seen in other contexts. In some cases, we are sure they are not, because the presence of a companion is likely to enhance mass loss, drive rotationally induced mixing, and make other changes over the life of any stars.

Data on binary populations in other galaxies are quite limited, but are generally consistent with these being similar to the Milky Way population. For instance, x-ray binaries have been found in all the larger galaxies of the LOCAL GROUP, and novae have been identified in galaxies as far away as the VIRGO CLUSTER, both in roughly the expected numbers. Good orbits for extragalactic binaries will require both the sensitivity of very large telescopes and the angular resolution possible only with adaptive optics or interferometry or from space.

Inventories

Many phenomena of stellar astronomy can be categorized by whether they occur only in interacting binary systems, preferentially in binaries, or reluctantly in binaries, and why. Most of the star types categorized this way below can be found in these volumes:

(a) Type I: Found only in binaries (roughly in evolutionary sequence).
- stars with well-determined masses;
- W Ursae Majoris variables;
- Beta Lyrae, W Serpentis and Algol variables;
- Zeta Aurigae stars;
- RS Canum Venaticorum stars;
- cataclysmic variables (including V 471 Tauri stars, novae, dwarf novae of several types, recurrent novae, symbiotic stars, nova-like variables and the magnetic DQ Herculis and AM Herculis variables);
- AM Canum Venaticorum stars;
- accretion-induced collapse (of white dwarfs to neutron stars or of neutron stars to black holes);
- x-ray sources (bright, compact, and not associated with rotation-powered pulsars; accretors can be neutron stars or black holes, donors of high or low mass).

(b) Type II: Types for which some or all of the promising models invoke binary systems, but where duplicity cannot always be demonstrated observationally.
- blue stragglers;
- barium stars (type stars with no technetium);
- dwarf carbon stars;
- anomalous (dwarf) Cepheid stars and SX Phoenices stars;
- millisecond pulsars with weak magnetic fields (some are definitely binaries with white dwarf or neutron star companions);
- type Ia supernovae;
- Thorne–Zytkow objects (red giants with neutron star cores; none actually known);
- type Ib and Ic supernovae (apparently from massive progenitors, but with their hydrogen-rich envelopes entirely stripped off);
- gamma-ray bursters.

(c) Type III: Favored in close binaries through effects of mass and angular momentum loss.
- Wolf–Rayet stars;
- Of and OBN stars;
- R Coronae Borealis and FG Sagittae stars (most are not known to have companions).

(d) Type IV: Inhibited in close binaries by gravitational effects.
    habitable planets;
    OBC stars;
    extended envelopes of massive stars needed for standard type II supernovae.
(e) Type V: Favored or inhibited in close binaries through the effects of synchronization of rotation to orbit period.
    BY Draconis and UV Ceti type flare stars;
    dynamo magnetic fields, stellar chromospheres and coronae, x-ray and radio emission star spots, and other indicators of stellar activity;
    Be stars;
    Delta Scuti stars;
    OB star winds;
    surface chemical peculiarities (due to diffusion) of types Am, Ap, Bp etc;
    surface chemical peculiarities (due to mixing and meridional circulation).

Update (24 December 2001)

Formation and statistical issues

Fragmentation continues to be regarded as the most important process in the formation of close binaries. An important observational discovery is that, among the very youngest stellar populations, triples are just about as common as binaries. The fate of a large fraction of these is to lose the smallest component (which then becomes an isolated BROWN DWARF or EXOPLANET), leaving the other two stars as a somewhat closer pair than they were before.

The number of binary and millisecond PULSARS, supposedly recycled in X-RAY BINARIES, continues to be much larger than the suggested progenitors can account for. Accretion-induced collapse, in which a white dwarf component is driven above the Chandrasekhar limit and so collapses to a NEUTRON STAR with rapid rotation and weak magnetic field without ever going through an X-ray binary phase, appears to be the most likely solution to this statistical mismatch.

Evolutionary issues

Early calculations of the evolution of close binaries were normally carried out under the assumption that the total mass and angular momentum of the system remained constant throughout. It has been clear for some time that this could not be true during late evolutionary phases (when single stars shed both gas and rotation in any case). More careful comparisons of observed properties of stars in binaries with such calculations show that the assumption of constant mass and angular momentum ('conservative' evolution) has failed even by the Algol phase.

The composition of the surface of the main sequence component of the black hole X-ray binary GRO 1655-40 shows evidence of accretion of material processed in nuclear reactions in the evolution and explosion of the progenitor star of the black hole. This shows that core-collapse type SUPERNOVAE can leave BLACK HOLES, as well as neutron stars, as their remnants.

Inventory issues

At least two kinds of binary star systems are now suspected of being the immediate progenitors of Type Ia supernovae. First are pairs consisting of a WHITE DWARF plus a hot subdwarf, with total mass exceeding the Chadrasekhar limit and with orbital periods short enough that the stars can spiral together in less than the age of the universe. One of these has now been found. The other is the class of recurrent novae, the subset of CATACLYSMIC VARIABLES whose white dwarf components have masses just a little smaller than the Chandrasekhar limit. It has been shown that the explosions in these, which we see as novae, do not expel as much material as was accreted to cause the explosion. Thus the mass of the white dwarf increases until the star begins to collapse and then burns most of its mass of carbon and oxygen violently to make the supernova.

The progenitors of the gamma ray bursters similarly now seem to include two sorts of object. One is binary pairs of neutron star + neutron star or neutron star + black hole. These probably make the bursts of gamma rays that last at most a few seconds. The other progenitor class is massive, very rapidly rotating (and perhaps binary) stars, whose cores collapse to rapidly rotating black holes with strong magnetic fields attached to their horizons or disks around them. These probably make the bursts that last many seconds to minutes, which are the sort for which X-ray, optical, and radio counterparts have now been found.

Binary System

As the name implies, a binary system normally consists of two stars, which are close together and therefore bound by a common gravitational field. Many binary systems have three or more components, however, and are often termed *multiple stars*. In many such cases there are two main components, additional members of the system being much smaller and often at considerable distance from the main pair. The majority of *double stars* are believed to be binaries, but observation over a period of years is needed to confirm their binary nature. A system whose orbital movement can be observed telescopically is termed a *visual binary*.

The stars comprising a binary system are each in orbital motion around their common centre of mass. Their orbits are similar in form but different in size, that of the less massive component being the larger. It is convenient for observational purposes, however, to study the apparent motion of the fainter star around the brighter; this is termed the 'relative orbit'. It is similar in shape to the actual orbits of both stars but larger than either, its major axis being equal to the sum of the major axes of the component orbits.

The orbital periods of visual binaries are very long (typically between 20 and 700 years), so determination of their relative orbits is a slow process requiring careful observation of the *separation* and *position angle* of the pair, repeated over many decades. A few binaries of very short period are known, for example the stars BD 8° 4352 (1.7 years) and δ Equulei (5.7 years), and some of exceptionally long period nevertheless have well-determined orbital elements, for example ε Sculptoris (period 1192 years) and 38 Geminorum (3190 years).

Close binary pairs, whose separation may be as little as one diameter of the primary star, cannot be observed by visual methods but their nature can be detected by other means. *Spectroscopic binaries* reveal their nature by periodic fluctuations in the Doppler shift of lines in their spectra; from these the varying *radial velocity* of the system can be determined and, over a period of time, the relative masses and orbit deduced. The first spectroscopic binary to be identified was the brighter component of the visual binary *Mizar*, which was shown from studies of line-doubling in its spectrum to be itself a binary of 20.5 days period, by Anna Maury (1866–1952) at the Harvard College Observatory in 1889.

Eclipsing binaries are close binary systems for which the Earth happens to lie in or close to the orbital plane of the system. The overall brightness of the system varies in a very regular manner, due to the components periodically eclipsing each other. The form of the *light curve* repeats very accurately, but its exact shape is specific to the particular star system; the relative size, mass and brightness, and the separation of the components, can be deduced from it. A well-known example is *Algol*, which has a period of 2.87 days.

Astrometric binaries are very close binary systems, usually comprising a fairly bright star with a much fainter companion. The existence of the latter is revealed only by a slight 'wave' in the *proper motion* of the bright star, determined from long-term astrometric measurements. The first to be discovered and best-known example is *Sirius* (apparent magnitude −1.44), whose eighth magnitude companion was discovered by Alvan Graham Clark (1832–1897) in 1862. It has a period of 50.09 years.

Binocular Astronomy

It is often supposed that anyone who means to take a serious interest in astronomy must acquire a large and expensive telescope. Nothing could be further from the truth. A great deal can be done with the naked eye alone, as is described in NAKED-EYE ASTRONOMY. It is true that a telescope costs a considerable amount of money, and the small, cheap telescopes on sale in camera shops are most unsatisfactory; the most that can be said for them is that they are slightly better than nothing at all. Luckily there is an alternative: obtain binoculars.

A pair of binoculars is essentially nothing more than two small refracting telescopes joined together. The main advantage is that the observer can use both eyes instead of only one. The FIELD OF VIEW will be much wider than that of a small astronomical telescope, and binoculars are handier, as they can easily be carried around. Moreover they give an erect image, which means they can equally well be used for activities such as bird-watching or looking at ships out to sea. The main disadvantage is that they have comparatively low magnification. Zoom binoculars can be obtained, but in general they are not satisfactory for astronomical observing, and in any case the maximum magnification is not likely to be much more than $\times 20$.

Binoculars are classified according to their magnifications and the diameters of their objective lenses (always given in millimeters). Thus 7×50 indicates a magnification of 7 with each objective lens 50 mm across; 12×50 gives a magnification of 12, again with 50 mm objective lens, and so on. At the outset, it is very important to make a careful decision about just which type is to be bought.

As with telescopes, the larger the aperture the greater the light-grasp, but there are hazards here. With increased power, the field of view becomes smaller, and the binoculars become heavier. If only one pair is to be obtained, then something around 7×50 is a good choice. The magnification is adequate, the field is pleasingly large, and the binoculars are light enough to be hand-held without any awkward shake. Once the magnification exceeds around $\times 12$, hand-holding is a major problem, and the only solution is to use some form of mounting.

The following notes may be useful as a general guide:

3×20: These binoculars are very light and can be slipped into one's pocket. They have their uses, but the low magnification means that they are decidedly limited, and unless they can be bought very cheaply, they are probably not to be recommended.

7×50: Binoculars of this kind are very common. They will show considerable detail on the MOON, for example, and almost endless superb star fields. For looking at some types of object, such as loose STAR CLUSTERS of the Pleiades type, they are ideal because of their large field of view.

8.5×50: Also very suitable. The light grasp is adequate, and the binoculars can be comfortably hand-held. The increased power means that more detail becomes available, though the field of view is noticeably reduced.

11×80: These too are common, though they are not cheap. The field of view is reasonably large, and the light grasp is excellent, though they are rather too heavy to be held steadily.

12×50: We are now reaching the limit of comfortable hand-holding. One solution is to sit down and jam one's elbows into one's body. This works fairly well, but it is not ideal.

With a magnification of over 12, a mounting is really essential. The obvious solution is a tripod. Most photographic shops sell binocular mounts which can be screwed into the top of an ordinary camera tripod, and this works well, though it is often necessary to perch the tripod on top of a platform or a solid table; otherwise you will have to be something of a contortionist when trying to observe an object high in the sky (incidentally, the same is true of small REFRACTING TELESCOPES, unless a right-angle prism is used).

Making a mount for a pair of binoculars is fairly simple for anyone who is reasonably good at carpentry, but the main essential, steadiness, must always be borne in mind. What is needed is the faculty of moving the binoculars freely in any direction, in ALTITUDE and in AZIMUTH. Another solution is to buy or make a 'neck mounting', in the form of a harness which can be attached to the observer's chest. This is effective, and if well made is not nearly so uncomfortable as might be thought.

It is of course possible to be more ambitious, and use a really powerful pair of binoculars. Some observers of VARIABLE STARS and COMET hunters often have binoculars with objective lenses up to six inches across. The cost is very high indeed, and the mounting is all important, so that binoculars with objective lenses of this kind will certainly not be found except in the hands of very serious researchers.

In short: if only one pair of binoculars is to be obtained, it is wise to choose a magnification of between 7 and 10, with an aperture of around 40–60 mm.

Selection is the first essential. One advantage of binoculars is that they can be tested on the spot. Check to make sure that both of the telescopes can be brought into sharp focus to produce a clear-cut image; if this cannot be done, reject the binoculars immediately. Check also for any trace of false color; this will indicate poor lens quality, and again the binoculars should be rejected. If possible, test upon a bright star, and ensure that the star can be reduced to a colorless pin-point of light (assuming, of course, that the star is a white one!). One more point is worth making here, though it ought to be obvious enough. As soon as you take the binoculars, loop the safety cord around your neck. If you fail to do so, then it will only be a matter of time before the binoculars are dropped, and a rapid descent to the ground will be no good to them at all.

Next, a word of warning: never use binoculars to look directly at the Sun, even with a dark filter over the eyepiece. If you do so, then you will focus the light and heat on your eyes, with tragic results. It is true that Mylar filters over the objective lenses can be used, and it is also possible to project the Sun's image onto a screen in the same way as is done for an ordinary telescope, but the results are never good, and in principle it is fair to say that the Sun should be avoided completely with binoculars (see also SUN: SAFE OBSERVATION).

The MOON is a different matter, because it sends us virtually no heat. With a low power and a full moon you may dazzle yourself, but that is all. In any case, full moon is the very worst time to observe, because there are virtually no shadows on the lunar surface—the sunlight is coming straight down, so to speak, and little can be seen apart from the broad, dark plains still known as seas. The best views are obtained when the Moon is in the crescent, half or GIBBOUS (three-quarter) stage. Look along the TERMINATOR—that is to say the boundary between the sunlit and the night hemispheres—and the craters and mountains will be beautifully displayed. The view alters from night to night, or even from hour to hour, as the angle of illumination changes. A crater which is prominent when on the terminator, with its floor wholly or partially filled with shadow, may be hard to identify when the Sun is high above it. Near full, the scene is dominated by the bright streaks or rays which are associated with a few of the craters, notably TYCHO (CRATER) in the Moon's southern uplands. It does not take long to learn one's way around the lunar surface, and binoculars are ideal for this purpose.

The situation is not so good from the point of view of the planetary enthusiast because of the relatively low magnification. MARS, for example, will appear as nothing more than a small, red disk. VENUS, which is closer to the Sun than we are, shows phases similar to those of the Moon, and during the crescent stage, either in the west after sunset, or in the east before dawn, the changing phase is easy to follow even with a magnification of no more than 7. Venus is so bright that it can often be seen even when the Sun is well above the horizon; remember, however, not to sweep around for it—you might look at the Sun by mistake. Similar restrictions apply when searching for the elusive planet MERCURY. Binoculars often show it, either soon after sunset or soon before sunrise. Again, never sweep for it with binoculars unless the Sun is completely below the horizon.

JUPITER is more interesting, because binoculars will show all four of the large satellites: IO, EUROPA, GANYMEDE and CALLISTO. They look like small stars close to Jupiter, and their movements from night to night are easy to follow. Saturn's rings (see SATURN: RINGS) are below binocular range, though with a magnification of 10 or more it is possible to make out that there is something unusual about the planet's shape. The two other planets, URANUS and NEPTUNE are available to binoculars, but they look like stars, and you will need a star map in order to locate them.

Then of course, there are comets. I have already referred to those serious comet hunters who scout the skies regularly and have made many discoveries. A really sound knowledge of star patterns is essential for this (real experts can memorize the positions and magnitudes of many thousands of stars so that a newcomer—either a comet or a nova—can be recognized at once). A bright comet is an ideal binocular object, and in recent years we have seen two: COMET HYAKUTAKE in 1996 and COMET HALE-BOPP in 1997. These were both superb, with long tails and gleaming heads. We cannot tell when the next brilliant comet will appear, but there are plenty of faint ones, and the binocular owner armed with a good star map will be able to identify them.

It is wrong to say that all stars look white. Some of them are colorless, but others are blue, yellow orange or red. Only really brilliant stars show obvious color as seen with the naked eye and these are mainly orange or red; for instance nobody can overlook the lovely warm glow of BETELGEUSE in ORION which contrasts so sharply with the pure white of Bigel in the Hunter's foot. With fainter stars the colors do not show up, and it is here that binoculars come into their own. Consider μCephei, in the far north of the sky, not too far from the Pole Star. It is so dim that it is very difficult to see without optical aid; turn binoculars toward it, however, and you will see why it has been nick-named the 'Garnet star'—it has even been likened to a glowing coal. This is only one of the many cases of stars which reveal their vivid hues when observed with binoculars.

Binary stars are also on view (see BINARY STARS—OVERVIEW). One of the best examples is ALBIREO, in Cygnus (the Swan). With the naked eye it looks commonplace enough, but binoculars show a golden yellow primary together with a vivid blue companion. Many binary stars are within binocular range, and there are also variable stars, many of which are orange or red. These are stars which fluctuate in brightness over short periods; binoculars make it possible to estimate their magnitudes, and to make really useful observations.

Star clusters are glorious; look for example in the Pleiades (or Seven Sisters) in Taurus, 'The Beehive' in the Crab and (from the southern part of the world) the Jewel Box cluster in the Southern Cross. Binoculars show that the Milky Way (see MILKY WAY GALAXY), which stretches across the sky from horizon to horizon, is made up of myriads of faint stars which appear so close together that they might be thought to be in danger of collision—though in fact we are dealing with nothing more than a line of sight effect, and stellar collisions very seldom occur.

GASEOUS NEBULAE, in which stars are being formed, are also to be seen; look at the Great Nebulae in Orion, close to the three stars of the Hunter's belt. Powerful binoculars even show the four stars of the 'Trapezium', which are silhouetted against the nebulosity and are responsible for making it shine. Then there are a few galaxies, vast external star systems so remote that light takes millions of years to reach us. The Great Spiral in ANDROMEDA, the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

nearest of the really large galaxies, is an easy binocular object, though it is true that photographs taken with adequate telescopes are needed to bring out its spiral form.

Binoculars are comparatively cheap, they are portable and they are easy to use. They can provide endless enjoyment, and can be also be used for serious scientific research. There can be absolutely no doubt that a pair of binoculars is much more valuable astronomically than a very small telescope.

Biot, Jean-Baptiste (1774–1862)

Physicist and astronomer, born in Paris, France, professor at the Collège de France. His most important work was on the polarization of light (which he correctly suggested was due to asymmetric molecules). With Joseph Louis Gay-Lussac he made in 1804 an ascent in a balloon to study a variety of phenomena at high altitude. Biot headed a commission from the Academy of Sciences to study the meteor shower at L'Aigle in 1803, from which two or three thousand pieces were recovered. In a turning point, the Academy, for many years stubbornly ridiculing the idea that meteorites fell from space, accepted Biot's report that the L'Aigle shower was extraterrestrial.

Birkeland, Kristian (1868–1917)

Birkeland was a Norwegian physicist, born in Oslo. In 1900, he identified and then simulated the charged electron–magnetic flux tube connection between the Sun and Earth that produces the aurora. He studied the zodiacal light during expeditions to the Sudan and Egypt. Birkeland committed suicide in a depression associated with the rejection of his auroral theories by his contemporary established scientists, but was later fully recognized as a founder of auroral studies (his portrait is on a Norwegian banknote). *Birkeland currents* are electric currents linking the Earth's ionosphere with more distant regions, flowing along magnetic field lines.

BiSON Network

The telescopes of the Birmingham Solar Oscillation Network (BiSON) are located in East and West Australia, South Africa, Chile, California and Tenerife. They permit continuous monitoring of the radial oscillations of the Sun using very narrow absorption lines of potassium in the solar atmosphere. Absorption cells of potassium vapor are used in the optical path of the telescopes to measure the precise wavelength of solar features and from this the Doppler motion of the Sun's surface can be detected to a precision of 1 cm s^{-1}. These velocities are analysed to detect oscillations in the Sun which give quantative clues to the temperature and density of the Sun's interior.

BL Lacertae

BL Lacertae (BL Lac or S4 2200+420) was known to be variable in the optical from as early as 1929, and because of its stellar appearance it was originally thought to be a VARIABLE STAR. It is located in the constellation Lacerta, the lizard (RA (J2000) = 22h 02′ 43.29″, DEC (J2000) = +42° 16′ 39.98″). Observations in the late 1960s showed it to have highly variable radio emission as well.

BL Lac was found to be an extragalactic object with the measurement of its redshift ($z = 0.069$, based on the detection of very weak emission lines) in the early 1970s. During the same period it was also understood to be an unusual type of ACTIVE GALACTIC NUCLEUS (AGN). Thus, BL Lacertae is the prototype of the class of AGN known as BL LACERTAE OBJECTS (also called BL Lacs). Collectively with some quasars such as 3C273 and 3C279, they are known as 'BLAZARS'. These objects are characterized as having bright nuclei with strongly polarized optical emission and large variability at all wavelengths. Their nonthermal radio–gamma-ray continua are thought to be emitted by a relativistic jet oriented close to the line of sight. BL Lac objects make up a small subset of AGNs, with about 350 known at present.

BL Lac is an important member of the class because it is relatively nearby, such that details can be well studied. The galaxy surrounding the active nucleus, or host galaxy, is a giant ELLIPTICAL GALAXY, typical of the host galaxies around other BL Lac objects.

Radio observations show BL Lac to exhibit SUPERLUMINAL MOTION, indicative of material being ejected at relativistic velocities from the nucleus. Recently, observations by the Compton Gamma-Ray Observatory showed BL Lac to be a strong gamma-ray source, together with many other blazars. The rapid variability timescales and high luminosities observed at these energies indicate that the gamma-rays are produced in a very compact region of the jet.

The nuclear emission in BL Lac is nonthermal and produces a continuum spectrum consisting of two components. The radio-to-ultraviolet spectrum is produced by synchrotron emission with peak power in the infrared–optical region while the x-ray-to-gamma-ray spectrum is produced by inverse Compton emission. (However, there are other possible explanations for this emission which are a subject of current debate.) These two components are present in all BL Lac objects.

BL Lac objects, as a class, are characterized by optical spectra which are featureless or which have extremely weak lines (less than 5 Å equivalent width). This property makes the determination of their distances difficult. BL Lac itself is no exception. Recently, however, strong, broad and variable emission lines (e.g. H-alpha, equivalent width = 7.3 Å, luminosity $\sim 2 \times 10^{41}$ erg cm^{-2} s^{-1}) appeared in the spectrum of BL Lac. Current thinking is that the lines appear when the variable continuum emission is low. Furthermore, the presence of emission lines indicates the presence of a radiation field external to the jet, which may play an important role in the jet energetics (providing seed photons for the inverse Compton emission responsible for the gamma-rays).

BL Lacertae Objects

BL Lacertae objects are an enigmatic group of ACTIVE GALACTIC NUCLEI (AGN) characterized by compact, flat-spectrum radio sources, nearly featureless and polarized optical continua, very luminous high-energy radiation (e.g. some BL Lacs are the only celestial detections at TeV energies; Macomb *et al* 1995) and rapid variability in all observed wavebands. In recent years, BL Lacs have been grouped with some quasars into the 'BLAZAR' class, which includes BL Lacs, flat-spectrum radio quasars, highly polarized quasars and optically, violently variable quasars. It is the absence of high equivalent width (typically $W_\lambda \leq$ 5 Å) emission lines which separates BL Lacs from the other blazar subclasses. A significant dilution of stellar absorption lines by a non-thermal continuum (typically a reduction of the Ca II 4000 Å 'break' by a factor of $\geq$1.5) separates BL Lacs from other low-power radio galaxies.

The absence of high-contrast emission and/or absorption lines also means that some BL Lacs have unknown REDSHIFTS, causing large uncertainties in their intrinsic properties. In fact, complete redshifts are not yet available for any flux-limited sample of these objects. Adding to the enigma of BL Lacs is that the class is often defined using operational 'negatives'; e.g., a BL Lac is an AGN which lacks strong emission or absorption lines. Defining membership in the BL Lac class using the absence of spectral lines can make membership dependent on the quality of the observational material in hand so that some quasars have been misidentified as BL Lacs on the basis of either poor-quality optical spectra or inadequate wavelength coverage (Antonucci and Ulvestad 1985). Also, relative variability between continuum and line-emitting regions can mean that an object might meet the 'featureless' criterion required for BL Lacs at one time but not at others (e.g. PKS 0521-365 and BL Lac itself, both of which have had high equivalent-width Hα emission appear in their spectra on some occasions; Stickel and Kuhr 1993; Vermeulen *et al* 1995). This leads to additional uncertainty in defining samples of BL Lacs for statistical studies.

This class of AGN is named for the first known example, BL LACERTAE, which, as the naming convention indicates, was discovered originally as a variable star. BL Lac was recognized to be a luminous radio source by Schmitt (1968), shown to have faint 'fuzz' surrounding its point source consistent with an ELLIPTICAL GALAXY at low redshift by Adams (1974) and proven to be extragalactic from the redshift of its 'fuzz' by Oke and Gunn (1974). Although one other 'variable star' was shown to be a BL Lac object (AP Libra), the early years of BL Lac research were dominated by studies of objects discovered as compact, flat-spectrum and time-variable radio sources.

Radio-loud BL Lacs (RBLs)

Approximately 75 BL Lacs have been discovered owing to their radio emission, including 37 in the 1 Jy sample of the radio-brightest BL Lacs in the sky (Stickel *et al* 1991). New large-angle sky surveys conducted with the VERY LARGE ARRAY are likely to contain several hundred more BL Lacs. No radio-quiet BL Lac Object has yet been discovered (Stocke *et al* 1990). Very-long-baseline interferometry of radio-selected BL Lacs (RBLs) has discovered that a large fraction (11 of 12 BL Lacs investigated by 1994; Gabuzda *et al* 1994) exhibit apparent SUPERLUMINAL MOTION, although at systematically lower velocities than for superluminal quasars (Cohen 1989). That superluminal motion should be observed in at least a few BL Lac objects is a natural prediction of the Blandford and Rees (1978) 'beaming model' for BL Lacs, in which the highly variable continuum emission from a relativistically moving 'jet' of particles ejected from an AGN (Begelman *et al* 1984) is 'beamed' in the direction of jet motion owing to the relativistic aberration of starlight effect. Lorentz factors γ as high as 40 have been inferred from this superluminal motion (see figure 1), although more typical values are $\gamma \sim$ 5–10 (Gabuzda *et al* 1994).

The combination of aberration and Doppler effect due to relativistically moving emission regions can brighten the observed jet luminosity $L_{\rm obs} = \delta^p L_0$ enormously, where

$$\delta = [\gamma(1 - \beta\cos\theta)]^{-1}. \qquad (1)$$

δ is termed the 'Doppler factor', θ is the 'viewing angle', the angle between the line of sight and the direction of emitting-particle motion, L_0 is the unbeamed, intrinsic jet luminosity, $\beta = v/c$ and $\gamma = (1 - \beta^2)^{-1/2}$. The exponent p is, in most cases, >1 but its exact value depends on the physical structure of the emitting region (see appendix B of Urry and Padovani, 1995 for details); typically $p = 2 + \alpha$ or $3 + \alpha$ in the cases of a continuous jet or discrete emitting blobs respectively, whose rest frame emission is isotropic with a power-law spectrum of the form $f(\nu) \sim \nu^{-\alpha}$. The Doppler factor is a strong function of viewing angle, especially for $\gamma > 5$ (see figure 2), so that, for typical values of the exponent p, relativistic beaming can boost the source output by a factor of several hundred. Doppler factors for BL Lacs have been inferred both from the observed luminosity functions and from details of the radio structure of BL Lacs compared with the same quantities for Fanaroff and Riley (1974) type 1 (FR-1) radio galaxies, the suspected 'parent population' of BL Lacs (see 'Parent populations' below). Typical values obtained are $\gamma \sim$ 5–10, although much larger values cannot be conclusively ruled out in some cases.

Thus, an AGN viewed from a direction nearly along the extension of its jet will have a spectral energy distribution (SED) dominated by this 'beamed' continuum radiation. There is overwhelming evidence that the emission mechanism in jets is incoherent synchrotron emission at lower energies and inverse-Compton emission at higher energies (the exact demarcation between emission mechanisms varies from object to object but is typically 0.1–10 keV; see Urry and Padovani 1995; Ulrich *et al* 1997; figure 5). Also, because this emission emerges from a very tiny region whose viewing angle can

Table 1. The properties of subclasses of BL Lacertae objects.

I. X-ray loud BL Lacs (XBLs)

- Low redshifts (≤ 0.6) and luminosities
- FR-1 (Fanaroff & Riley type 1) radio morphologies and power levels
- Weak optical absorption lines
- Weakly variable optically ($\delta m \leq 1$ mag)
- Weakly optically polarized ($\leq 5\%$)
- Many have 'preferred' position angles of polarization
- Relatively weak high energy (inverse-Compton) emission
- $\langle V/V_{\rm max}\rangle < 0.5$
- Most XBLs are HBLs (see below)

II. Radio loud BL Lacs (RBLs)

- Mixture of high and low-redshift and luminosity objects
- Mixture of FR-1 AND FR-2 ('classical doubles') radio morphologies and power levels
- Many possess weak optical emission lines
- Some highly variable optically ($\delta m \geq 1$ mag)
- Some possess high ($\geq 10\%$) and highly variable optical polarization
- Relatively strong inverse-Compton emission
- $\langle V/V_{\rm max}\rangle > 0.5$
- Most RBLs are LBLs (see below)

III. Low-energy peaked BL Lacs (LBLs)

- Spectral energy distribution peaks in the IR

IV. High-energy peaked BL Lacs (HBLs)

- Spectral energy distribution peaks in the UV/x-ray

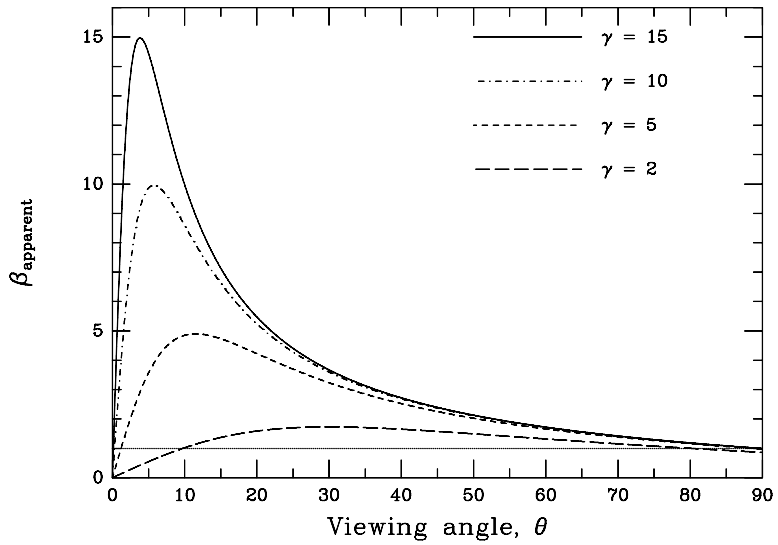

Figure 1. The apparent velocity relative to the speed of light $\beta_{\rm app}$ versus angle to the line of sight θ for an object approaching at relativistic speed. Different curves correspond to different Lorentz factors γ. Note that $\beta_{\rm app}$ is essentially independent of γ at large angles. From Urry and Padovani (1995), copyright Astronomical Society of the Pacific, reproduced with permission from the authors.

change rapidly, the BL Lac SED can be highly variable on short timescales ($\ll$1 day; Doxsey *et al* 1983; Moore *et al* 1985), highly polarized owing to a small-scale ordering of magnetic fields (see compilation in Angel and Stockman 1980) as well as overwhelm any isotropic radiation from the AGN nuclear or near-nuclear region (e.g. broad or narrow emission line clouds in the optical–UV, accretion disk emission in the UV or high-energy coronal emission in the hard x-ray). Thus, in the 'beaming model', the BL Lac SED is dominated in all observed wavebands by beamed jet emission.

The very rapid variability of BL Lac (and other blazar) radio emission sets a maximum size based on light-travel arguments (i.e. a size smaller than the distance traversed by light during the variability timescale) and thus a minimum photon density for the synchrotron-

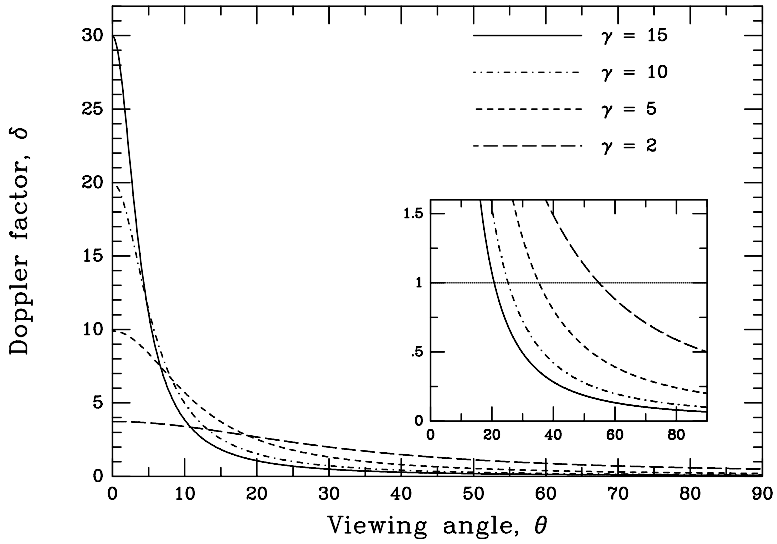

Figure 2. The dependence of the Doppler factor δ on the angle to the line of sight θ. Different curves correspond to different Lorentz factors γ. The expanded scale on the inset shows the angles for which δ=1. From Urry and Padovani (1995), copyright Astronomical Society of the Pacific, reproduced with permission from the authors.

emitting region which would create far more x-ray photons by the inverse-Compton process than is observed. This 'Compton catastrophe' (Hoyle *et al* 1966) leads to the conclusion that the blazar emission regions must be moving relativistically so the light we observe is not emitted isotropically and the variabililty timescales appear shortened. The ratio of predicted to observed inverse-Compton emission sets a lower limit on the Doppler factor, δ (cf equation (1)), which can explain this deficiency (Jones *et al* 1974). A similar argument based on γ-ray variability of blazars leads to $\delta > 6$ (Maraschi *et al* 1994), while the Compton catastrophe requires similar or even larger values of γ. Multiwavelength monitoring of BL Lac objects and blazars has been instrumental in proving that the high-energy (MeV to TeV) emission mechanism is inverse-Compton scattering within a relativistically moving jet although the location of the seed photons for this process is still debatable (Ulrich *et al* 1997). This type of observation has the potential of probing jet physics not decipherable otherwise.

X-ray loud BL Lacs (XBLs)

Because of the advent of satellite x-ray observatories, ~200 new BL Lacs have been discovered owing to their substantial high-energy luminosities, including 43 BL Lacs discovered in the Einstein Extended Medium Sensitivity Survey (EMSS; Morris *et al* 1991; Rector *et al* 2000). The vast ROSAT databases (all-sky survey and multitude of pointed observations) contain several hundred more BL Lacs that are just starting to become identified (e.g. Bade *et al* 1998). These new samples are beginning to show that the XBLs and RBLs are probably the extremes of a single population of BL Lacs (e.g. Laurent-Muelheisen *et al* 1998). However, there is also considerable evidence against this unification because, while XBLs share many of the qualities of RBLs described above, there are also significant differences between these two types including the following (see table 1 summary).

(1) Significantly higher redshifts have been measured for RBLs (e.g. $\langle z \rangle \approx 0.6$ for the 1 Jy sample; Rector and Stocke 2000; $\langle z \rangle \approx 0.3$ for the EMSS; Rector *et al* 2000). Not suprisingly, many high radio power objects are found in RBL samples but none is found among XBLs. Also, for complete samples, $\langle V/V_{\rm max} \rangle = 0.61 \pm 0.05$ for RBLs (1 Jy sample; Stickel *et al* 1991) and $\langle V/V_{\rm max} \rangle = 0.40 \pm 0.05$ for XBLs (EMSS sample; Rector *et al* 2000). Because the $\langle V/V_{\rm max} \rangle$ test allows a simple assessment of cosmological evolution using complete samples, the inference from these mean values is that RBLs were numerous and/or more luminous in the past than now and XBLs less so. For reference, $\langle V/V_{\rm max} \rangle = 0.5 \pm (12N)^{-1/2}$ is the expectation value for a complete, flux-limited sample of objects that shows no evolution (where N is the number of objects in the sample).

(2) Most BL Lacs show compact, distorted radio morphologies consistent with a highly beamed object. However, some RBLs exhibit extended radio morphologies of high-power 'classical doubles' (Fanaroff and Riley 1974 type 2 sources; FR-2s), commensurate with the radio power of their extended (and so presumably 'unbeamed') radio power levels (Kollgaard *et al* 1992; Rector and Stocke 2000). In contrast, XBLs show extended radio morphologies and power levels of low-power (FR-1) radio sources. Figure 3 shows examples of RBL and XBL radio structure.

(3) The optical spectra of RBLs and XBLs are systematically different in detail. While both are nearly 'featureless', XBLs often show weak absorption lines

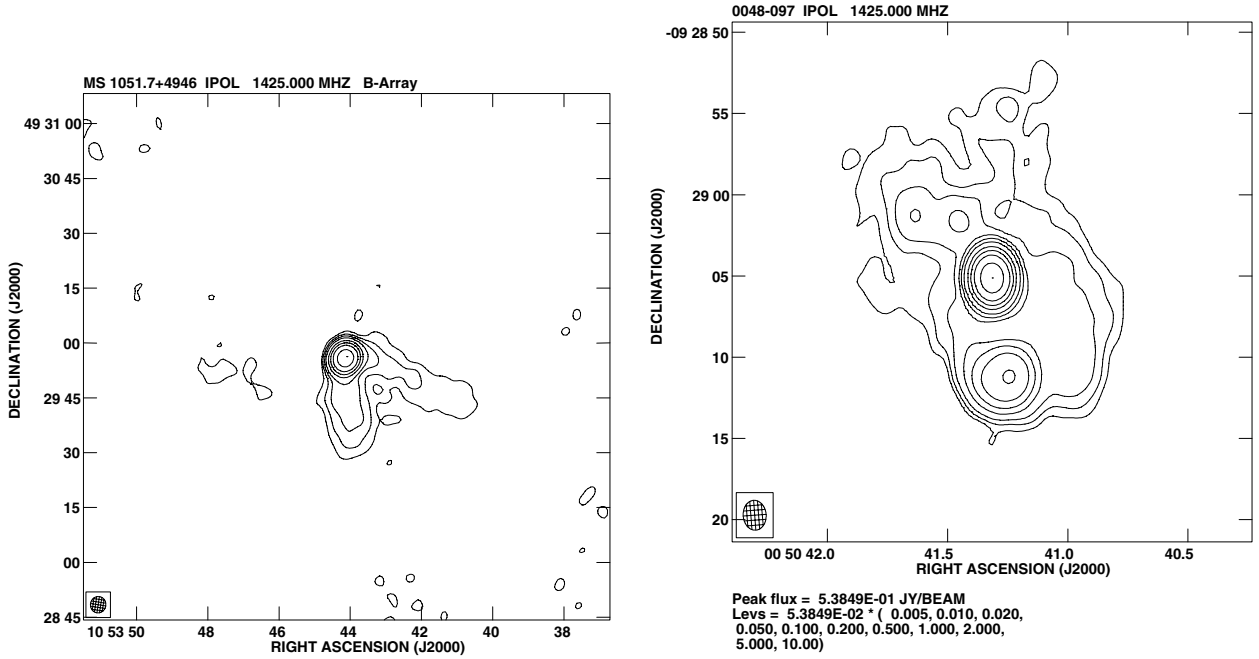

Figure 3. VLA radio maps for representative BL Lac objects. MS 1051.7+4946 (an XBL shown at left; Rector *et al* 1999) has an extended radio power (10^{24} W Hz^{-1}) and morphology typical of FR-1s (in this case the morphology of a head-tail radio galaxy). In contrast, some RBLs have extended structures which are much too luminous to be FR-1s and extended radio morphologies which resemble bent classical doubles (e.g. the RBL 1 Jy 0048-097, shown at right, has an extended radio power of $10^{26.2}$ W Hz^{-1}; Rector and Stocke 2000).

in their spectra (Morris *et al* 1991) consistent with an underlying older population of stars, as expected from deep optical imaging which reveals giant elliptical galaxies surrounding the BL Lac nucleus (Wurtz *et al* 1996; Urry *et al* 1999). While the closer RBLs are also in giant ellipticals (Wurtz *et al* 1996), the nature of the host galaxies of $z \geq 0.7$ RBLs is not known. It is the spectra of these more distant RBLs that often show weak emission lines in their spectra, unlike the XBLs. As with item (2), the weak emission lines in RBLs suggest a closer relationship between some RBLs and other blazar classes (e.g. the flat spectrum radio quasars) than do the XBLs and lower-z RBLs. Examples of high signal-to-noise ratio optical spectra of BL Lacs are shown in figure 4.

(4) While almost all BL Lac objects have overall SEDs which are very simple compared with quasars in exhibiting an overall parabolic shape with no signs of dust or accretion disk emission, some BL Lacs have SEDs which peak in the infrared (so-called 'low-energy-peaked' BL Lacs or LBLs) while others peak in the UV and x-ray ('high-energy-peaked' BL Lacs or HBLs; Sambruna *et al* 1996; Padovani and Giommi 1995). Most RBLs are LBLs and most XBLs are HBLs. Further, RBLs exhibit broadband SEDs which more closely match other blazar classes than XBLs (e.g. Brinkmann *et al* 1996). Examples of LBL and HBL SEDs are shown in figure 5.

(5) While RBLs have polarized flux fractions as high as other blazars, XBLs are more modestly polarized (Jannuzi *et al* 1994). Moreover, RBL polarizations vary considerably in both percentage and position angle, sometimes on very short timescales (<1 day; Moore *et al* 1985). Quite surprisingly, many XBL polarization vectors are quasi-stationary over long time periods (months to years; Jannuzi *et al* 1994).

The above similarities and differences between these types of BL Lacs are not easily explicable by means of a single, easily understood model. Several items, particularly the XBL trait of stable polarization position angles, strongly suggest a viewing-angle difference wherein XBLs are viewed further off the jet outflow axis than RBLs. However, the difference between the SED peaks of HBLs and LBLs is much too large to be determined by viewing angle differences alone if $\gamma \approx 3$–5 for BL Lacs. Further, since the emission line and extended radio luminosities, redshift distributions and evolutionary trends for these objects should be independent of viewing angle, differences in these observables between RBLs and XBLs are not easily explained with a simple viewing-angle hypothesis either.

For these and other reasons, models modifying the viewing-angle hypothesis have been proposed. Padovani and Giommi (1995) have suggested that XBLs simply possess a different high-energy cutoff in their electron energy distributions to RBLs. However, this model ignores orientation, which, as discussed above, is clearly important in BL Lac objects. Georganopolous and Marscher (1998) have devised a two-parameter model in which the observed properties of BL Lacs can be explained

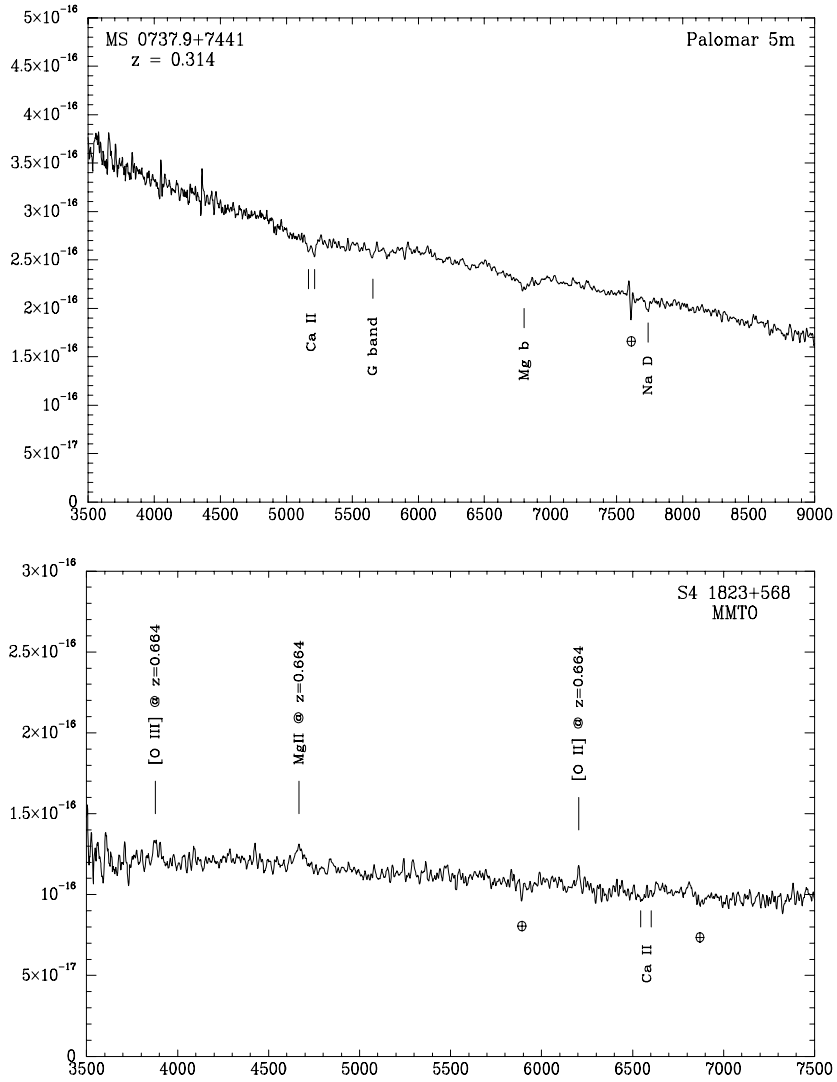

Figure 4. Representative optical spectra of BL Lac objects from the Multiple Mirror Telescope Observatory (MMTO) and from the Palomar 5 m. The spectrum of the XBL MS 0737.9+7441 (shown at top; Morris *et al* 1991) has only weak absorption features, diluted by a luminous nonthermal continuum. The spectrum of the RBL S4 1823+568 (shown at bottom; Rector and Stocke 2000) exhibits weak but moderately luminous emission lines. A few XBL and RBL spectra remain completely featureless despite heroic efforts to detect either emission or absorption lines.

by both the orientation and the electron kinetic luminosity of the jet. Their model can fit much of the data described above; however, it too is not without problems (e.g. Giommi *et al* 1999).

'Parent populations'

Given that BL Lac objects are thought to be dominated by relativistically-beamed and Doppler-boosted radiation from an outwardly moving jet seen nearly on axis, one might ask, 'what would such an object look like well away from the jet outflow axis, where the effects of beaming are negligible?' Such objects are termed the BL Lac 'parent population'. Clues concerning the parent population of BL Lacs primarily come from emission thought be isotropic (i.e. extended optical light from the 'host' galaxy, emission-line regions or extended radio emission) or from the BL Lac space density and redshift evolution.

The first identification of the 'parents' of BL Lacs came from the observed local space density of BL Lacs (Schwartz and Ku 1983). BL Lacs are simply too numerous in the local universe to be any other type of AGN than 'beamed' low-power radio galaxies (FR-1s). That is, BL Lacs at $L_x > 10^{44}$ erg s^{-1} have space densities of 10^{-7} Gpc^{-3} (Morris *et al* 1991) while FR-1 radio galaxies have space densities of 10^{-5} Gpc^{-3}, easily providing enough 'parents' for BL Lacs. Higher power FR-2 radio sources and Seyfert galaxies are actually less numerous than BL Lacs in the nearby Universe, ruling them out as parents. Urry

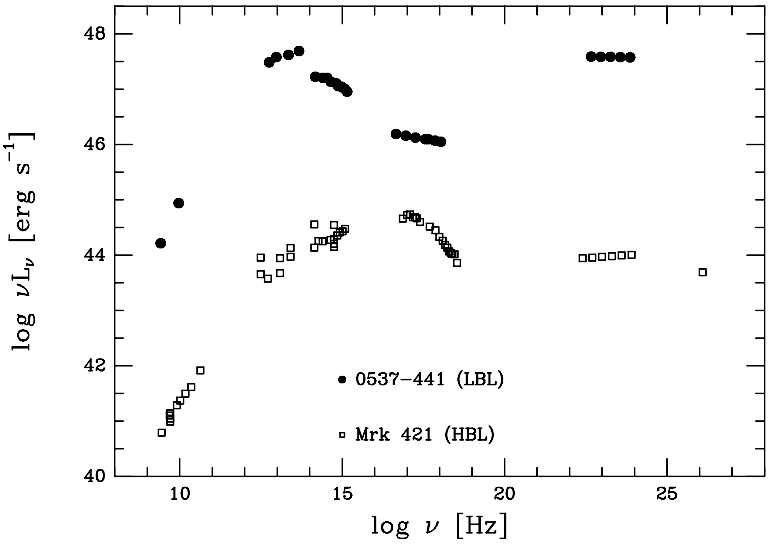

Figure 5. The SEDs of a typical RBL (PKS 0537-441) and a typical XBL (Mrk 421). RBL SEDs peak in the infrared–optical region (and are so-called 'low-energy-peaked' BL Lacs or LBL^{-1}) with extremely luminous inverse-Compton emission at high energy while XBL SEDs peak in the UV–x-ray region (and are 'high-energy-peaked' BL Lacs or HBLs) and have relatively weaker inverse-Compton emission. From Urry & Padovani (1995), copyright Astronomical Society of the Pacific, reproduced with permission from the authors.

and Shafer (1984) extended these studies significantly by constructing theoretical luminosity functions for 'beamed' objects, which showed that the luminosity function of a beamed population is flatter than that of the parent population. Subsequent papers by Urry and collaborators (see summary in Urry and Padovani 1995) used these theoretical luminosity functions to build a plausibility argument that BL Lacs are beamed FR-1 radio galaxies. Their work also suggests that only modest values of $\gamma \sim 3$–5 are required to 'boost' the luminosity function of FR-1s into the observed BL Lac luminosity function.

Very similar ranges of γ are also obtained from studies of BL Lac radio emission from 'core dominance' values (defined as the ratio of core to extended flux). BL Lacs are observed to have much higher core dominance values than FR-1s (1–30 for BL Lacs compared with 0.01–1 for FR-1s; see Wardle *et al* 1984, who first applied this method), which implies a Doppler factor $\delta \sim 30$ and thus viewing angles of a few degrees for Lorentz factors of $\gamma \sim 5$–10. However, some high-z RBLs have much higher core dominance values ($\gg$1000; Rector and Stocke 2000) and so are not easily accommodated by this picture. Further, while all XBLs have extended, and thus unbeamed, radio power levels consistent with being FR-1s, only half of the 1 Jy RBL sample are even plausibly FR-1s on the basis of their extended radio power levels; the other 50% of RBLs are too luminous to be FR-1s (Kollgaard *et al* 1992; Rector and Stocke 2000). Since FR-1 radio galaxies also lack luminous emission lines in their optical spectra, a combination of extended radio power levels and emission line properties suggests that only half (primarily the lower-z half) of the 1 Jy RBLs are plausibly FR-1s. Also, $\langle V/V_{\rm max}\rangle = 0.42 \pm 0.05$ for FR-1s (Urry and Padovani 1995) matches XBLs but not RBLs.

Optical imaging of host galaxies of BL Lacs (e.g. Wurtz *et al* 1996; Urry *et al* 1999) show convincingly that almost all BL Lacs have giant elliptical galaxies as 'hosts', which is generally consistent with the beamed FR-1 hypothesis. However, these BL Lac hosts may be a bit too faint as a class (Wurtz *et al* 1996) and in environments too poor (Wurtz et al. 1997) to match FR-1s precisely (FR-1s are often found in very rich clusters whereas BL Lacs are not). This slight inconsistency might be remedied if, for some reason, BL Lacs that are associated with the brightest cluster galaxies in rich clusters were being overlooked (i.e. misclassified as something else).

In summary, XBLs have characteristics entirely consistent with being beamed FR-1s, but only about half of all RBLs are consistent with being beamed FR-1s. The remaining, primarily high-z, RBLs are more consistent with being beamed FR-2s.

Are some BL Lacs gravitationally lensed quasars?

A continuing annoyance, and a contentious topic, of BL Lac research is whether or not gravitational 'MICROLENSING' plays a part in the appearance of some BL Lac objects. Microlensing is caused by GRAVITATIONAL LENSING of a background source by a foreground star or group of stars, creating multiple images that are microarcseconds in separation. As such, microlensing preferentially amplifies the brightness of smaller regions (down to the size of the lens itself) compared with more extended regions. Microlensing is suspected in the case of several BL Lac objects (see, e.g., Schneider *et al* 1992, p 433) because it can create one of the basic observational signatures of BL Lac objects: the very-low-contrast emission lines. In this scenario, the non-thermal continuum emission region

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of a relatively normal background quasar is microlensed and amplified by foreground stars (e.g. in an intervening galaxy), thereby 'swamping' the emission lines and creating the appearance of a BL Lac.

It is now generally accepted that most, if not all, BL Lacs, are not microlensed background quasars (a hypothesis proposed by Ostriker and Vietri 1985, 1990). Still, over the years there have been several individual cases identified that are suspicious in this regard, of which AO 0235+164 is a famous example. This BL Lac is unusual in having two foreground Mg II absorption lines in its spectrum which match the redshifts of galaxies close on the sky to the BL Lac (e.g. Yanny *et al* 1989). The fast time variability of the H I 21 cm absorption line associated with one of these Mg II absorbers (Wolfe *et al* 1978) has not been explained satisfactorily using standard interpretations but is explicable using gravitational lensing scenarios. Currently there is only one confirmed case of a lensed BL Lac, the 'smallest Einstein ring' source B2 0218+357, which shows a compact ring from macrolensing. However, to this date no individual BL Lac has been proven to be due to a microlensing event. However, circumstantial evidence continues to arise; e.g., as Stocke and Rector (1997) recently noted, the 1 Jy RBL sample has a large excess of large equivalent width foreground Mg II absorbers as compared with quasars, a correlation which, if real, can be accounted for easily only in a microlensing scenario.

Conclusions

While BL Lacertae objects represent a small fraction of all AGN known, they are the only class of AGN that appear to have emission that is dominated at all wavebands by relativistically beamed jet emission. Therefore, BL Lacs routinely exhibit several unusual properties that are not common among AGN in general, including luminous emission at all wavelengths (from radio to γ-ray), apparent superluminal motion, high and rapidly variable continuum polarization, rapid time variability (especially at radio, x-ray and γ-ray frequencies), and nearly featureless UV, optical and near-IR spectra. Relativistic beaming is an essential ingredient in explaining the observed properties of BL Lacs. However, it has also become clear that a relativistically beamed jet viewed at different angles is insufficient by itself to explain both the diversity of BL Lac properties and the differences between BL Lacs and any proposed 'parent population'. Therefore, BL Lacs remain a fascinating area for future astrophysical research, not only because these AGN offer a unique opportunity to scrutinize our understandings of jet physics, but also because they remain the most enigmatic class of AGN over 25 yr after their discovery.

Blaauw, Adriaan (1914–)

Dutch astronomer, worked at Leiden, Yerkes and Groningen, where he built up the Kapteyn Astronomical Laboratory to concentrate on galactic structure. He himself studied the motions of star clusters and associations,'runaway stars' (ejected from a close double star when one of them explodes as a supernova), star formation and the cosmic distance scale. Blaauw led the foundation of the European Southern Observatory, of which he was Director General in the years 1970–1974. He was President of the International Astronomical Union in the years 1976–1979.

Black Drop

An optical phenomenon observed at the beginning and end of transits of Venus across the Sun's disk in which the dark silhouette of Venus, having just wholly passed onto the Sun's disk at one limb, or being just about to make contact with the opposite limb, is seen to be 'connected' to the limb by a narrow dark 'bridge'. This bridge is the so-called black drop. It was probably first observed at the transit of 1761; Mikhail Lomonsov concluded that it signified the presence of an atmosphere, and it is indeed caused by the refraction of sunlight through Venus's atmosphere. It has to be allowed for when timings are made of transits. Failure to appreciate this reduced the accuracy of early measurements of the solar parallax (from which the Earth–Sun distance is derived) made by timing transits of Venus from different locations on the Earth's surface. However, there may be a subjective aspect to the appearance of the black drop, for it has occasionally been reported at transits of Mercury, which has only the most tenuous of atmospheres.

Black Eye Galaxy

Popular name for the spiral galaxy, M64, in the constellation of Coma Berenices. It has unusually smooth spiral arms and a very prominent dark lane of dust outside its nucleus, its name deriving from the presence of this conspicuous dark patch. Designated as an Sb galaxy in the Hubble classification scheme, it lies at a distance of about 12 million light-years, and has a diameter of about 65 000 light-years.

See also: Hubble classification, interstellar absorption lines, Messier Catalog, spiral arms, spiral galaxy.

Black Hole

A region of space into which matter has fallen and from which no material object, light or signal of any kind can escape. In other words, within this region of space, the gravitational field is too powerful to let anything escape.

The basic concept is not new and, in a sense, dates back to the suggestion made in 1783 by John Michell and in 1798 by Pierre Laplace that there might exist in the universe massive bodies which would be quite invisible because the force of gravity at their surfaces would be too great to allow light to escape. At the surface of such a body the escape velocity would be greater than the speed of light. Current models of black holes are based on the general theory of relativity, from which it can be shown that if any given amount of matter is compressed sufficiently, so that it is contained within a critical radius known as the Schwarzschild radius, no signal can ever escape from it.

A black hole would arise if a quantity of matter were compressed inside its Schwarzschild radius, and the boundary of the black hole (known as the event horizon) would be a sphere having this radius. Nothing that falls inside can ever escape again. It is important to note that a black hole is not a solid body. It is a region of space whose radius depends only on the amount of matter that has fallen inside. What happens to that matter thereafter has no bearing on the hole's size, and any matter which subsequently falls in only serves to increase the radius of the hole.

The Schwarzschild radius is normally very small. For the Sun, it is only 3 km, and if, in some way, the Earth could be compressed within its Schwarzschild radius, the resulting black hole would be only the size of a marble.

Black holes will probably have been formed as a result of the collapse of the most massive stars as they run out of fuel at the end of their life cycles. Most stars collapse to form dense compact objects, but the most massive stars will continue to collapse until, in principle, all their matter is compressed into a point of infinite density known as a singularity. Before this happens, the shrinking star will have passed inside its Schwarzschild radius, giving rise to a black hole, and disappearing forever from view.

Black holes are important energy sources, as matter falling in towards a black hole, before crossing the event horizon, may release considerable amounts of gravitational potential energy. A rotating black hole (essentially similar to the simple stationary one described above) is even more efficient in this respect. Not surprisingly, black holes have been canvassed as possible 'explanations' of hitherto unexplained energy sources in the universe.

The most hopeful way in which black holes may be detected is by looking for their effects on matter in their vicinity. For example, if a black hole is a member of a binary system, then the visible star will be seen to follow an orbit round an invisible object. Again, if material is falling into a black hole, it will become excessively heated and will emit x-rays. There are a number of possible candidates under investigation, the first identified being Cygnus X-1, which is an x-ray source retaining a massive invisible object. The case of V404 Cygni is even more convincing.

Some black holes appear to have non-stellar origins. Large volumes of interstellar gas or large numbers of stars could collect and collapse into supermassive black holes at the centers of quasars and galactic systems that appear to be exploding. The enormous energy output of such objects could be accounted for by the collapse of billions of solar masses into a large black hole. In 1994, the Hubble Space Telescope provided evidence for the existence of such a supermassive black hole at the center of the galaxy M87. It has a mass of two or three billion Suns but is no larger than the solar system. In 1999, the Japanese x-ray satellite ASCA identified general relativistic effects in the supermassive black hole MCG-6-30-15, recording speeds up to $c/3$ in material orbiting 6 Schwarzchild radii from the black hole. This was the first time that general relativistic effects had been directly connected to a black hole candidate. In 2001, high-quality infrared spectra of the nucleus of Centaurus A obtained with the ISAAC instrument at the European Southern Observatory (ESO) Very Large Telescope (VLT) showed that there is a 200 million solar mass black hole at its center. The infrared spectra showed the characteristic shape of a rotating disk. High-speed motions of the gas in this disk were detected; this is the hallmark of a black hole. An analysis of the rotational speed of the disk leads to a determination of the total mass of the material inside the disk as more than 200 million solar masses—too much to be due to normal stars.

Another kind of non-stellar black hole has been proposed by the British astrophysicist Stephen Hawking. According to the theory, numerous tiny primordial black holes with masses less than an asteroid could have been created at the time of the Big Bang. These mini black holes lose mass over time and disappear.

Black-Body Radiation

An ideal emitter or absorber of radiation is called a black body. A perfect black body will absorb all radiation that falls on it, and will emit radiation that has a continuous spectrum determined only by the temperature of the black body. The distribution of energy radiated against wavelength follows a curve known as a black-body (or Planck) spectrum and, for a given temperature, there is a particular wavelength at which the maximum emission takes place.

According to the Wien displacement law, the wavelength at which a black body emits its maximum quantity of radiation is inversely proportional to its absolute temperature. This law may be used to give the approximate wavelength, λ_{max}, at which a star of effective temperature T_e has its peak emission; expressing wavelength in nanometers (nm):

$$\lambda_{max} = 2.89 \times 10^6 / T_e$$

where T_e is expressed in kelvin.

Stars and hot solid bodies are not perfect black bodies, but their radiation can be described in terms of black-body properties.

Black-Hole Candidates in X-ray Binaries

X-ray binaries are short-period (hours to days) interacting binaries in which one component is an (almost) normal star transferring material onto its compact companion via an ACCRETION DISK around the compact object. Matter spirals in the intense gravitational field, eventually falling onto the surface of the compact companion, which can be a white dwarf, neutron star or black hole. However, the x-ray luminosities generated in this accretion process are so high (sometimes $>10^{38}$erg s^{-1}) that a white dwarf can (usually) be excluded. Also while the presence of regular pulsations (usually $\sim$ seconds) indicates that the compact object must be a neutron star (a PULSAR), the absence of this signature does not automatically mean it must be a black hole. Only direct measurement of the compact object mass (from the normal star's orbital motion around the unseen compact object) can determine this. By simple application of Kepler's laws it is possible, with minimal assumptions, to infer the minimum mass of the compact object. If it exceeds a certain value (theory suggests this maximum to be $3.2M_\odot$, while observationally no confirmed neutron star exceeds $2M_\odot$) then it is declared to be a black-hole candidate on the grounds that a neutron star cannot then support itself without collapsing. Also if general relativity (GR) is the correct physical description of gravity, then such an object can only be a BLACK HOLE (see also GENERAL RELATIVITY TESTS: BINARY PULSARS). Determining the *maximum* mass of a neutron star accurately therefore has important repercussions for the nature of matter at nuclear densities.

If the mass-losing star is significantly *less* massive than the compact object (the so-called *low-mass x-ray binaries* or LMXBs), then these mass estimates provide a firm *lower* limit to the compact object's mass which is of great importance. Effectively the companion is being used as a test particle in orbit about the compact object, analogous to the (extremely low mass) planets orbiting our Sun. All-sky monitors on space-borne x-ray observatories have led to the discovery of soft x-ray transients (SXTs, so called because of their low x-ray temperatures), a class of object which produces rare, dramatic x-ray outbursts (typically separated by decades), followed by an extended period of x-ray inactivity (see also X-RAY BINARY STARS). It is only during this time that their mass-losing companions are visible, making them virtually the only class of LMXB for which dynamical mass studies are possible. More than two dozen SXTs are known, of which $\sim$10 have produced accurate mass determinations, the heaviest of which (V404 Cyg) is $12M_\odot$.

Dynamical mass measurements

A detailed knowledge of binary parameters for many of the high-mass x-ray binaries (HMXBs) (which have easily identified early-type, massive companions) is due to their pulsating neutron star compact objects. They are effectively *double-lined spectroscopic binaries*, in which each component produces a radial velocity curve (the neutron star pulsation period is also modulated by the Doppler effect). The amplitudes of these curves are K_X and K_2 (for the compact object and secondary star respectively), the ratio of which is their mass ratio, q. With an orbital period of P then Kepler's third law allows $f(M)$, the *mass function*, to be determined for each component:

$$f(M_X) = \frac{PK_2^3}{2\pi G} = \frac{M_X^3 \sin^3 i}{(M_X + M_2)^2} \quad (1)$$

$$f(M_2) = \frac{PK_X^3}{2\pi G} = \frac{M_2^3 \sin^3 i}{(M_X + M_2)^2} \quad (2)$$

where i is the orbital inclination. If the systems are eclipsing (which constrains i) then M_X and M_2 can be determined. Such work has produced the detailed dynamical mass measurements of neutron stars that are summarized in figure 1 together with the mass measurements from binary radio pulsars. All these masses are consistent with a mass of $(1.35 \pm 0.04)M_\odot$.

However, when HMXBs are suspected of harboring black holes (as in Cyg X-1 and LMC X-3), the mass measurement process is less straightforward. By definition, there will be no dynamic features (such as pulsations) observable from the compact object, and so these are *single-lined spectroscopic binaries* with only K_2, and hence $f(M_X)$, being measurable. Also, since $M_2 > M_X$, then M_X cannot be accurately determined without constraints on the value of M_2. Unfortunately, there is usually a wide range of uncertainty in M_2 ($\sim$12–20 $M_\odot$ for Cyg X-1) because of the (necessarily) unusual evolutionary history of the binary. Nevertheless the compact object in Cyg X-1 almost certainly is a black hole, since the available data constrain it to be $>3.8M_\odot$, which is just above the canonical maximum mass of a neutron star.

Low-mass x-ray binaries

However, when the mass-losing star is of low mass (the LMXBs), then the situation is very different. Such short-period x-ray binaries will have very faint companion stars, which leads to the major observational problem that the observed optical light will be dominated by reprocessed x-radiation from the accretion disk (or heated face of the companion star). This is why the optical spectra of LMXBs are hot, blue continua (U–B typically -1) with superposed (usually weak) broad hydrogen and helium emission lines, the velocities of which indicate that they largely arise in the inner disk region. This normally prevents the observation of any useful dynamical information associated with either component in the binary. Hence, the evidence for the nature of the compact object in most LMXBs has come indirectly, usually from the detection of x-ray bursts (as few are x-ray pulsars; see X-RAY BURSTERS) or the fast flickering first seen in Cyg X-1 (and hence frequently used as a black-hole 'indicator', although it too is also seen in NEUTRON STAR systems).

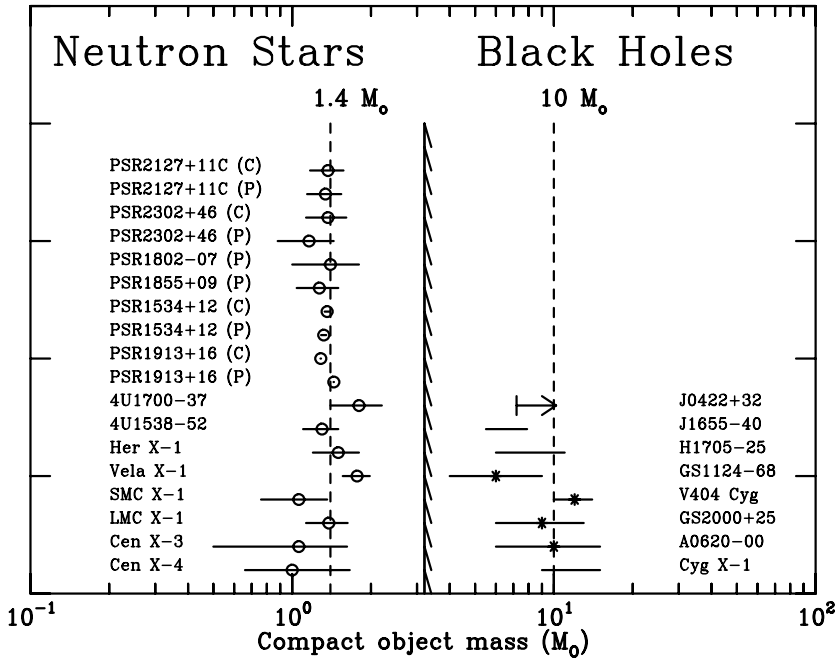

Figure 1. The distribution of neutron star and black-hole masses in binary systems.

Soft x-ray transients

It is therefore necessary to find sources where the x-ray emission switches off for some reason, so that the companion star can become visible. This is the basis of the new field of study of the SXTs (sometimes referred to as x-ray novae), which contain a remarkably high fraction (∼75%) of black-hole candidates. Only six SXTs are confirmed neutron star systems in that they display type I x-ray bursts. The observed properties of SXTs are summarized as follows.

- *X-ray transient outbursts*, reaching a typical peak x-ray luminosity of $\sim 10^{37-39}$erg s^{-1}. Erratic variability on short timescales is often present. Several new transients are found each year.
- *Fast-rise, exponential decay light curves*, with timescales ∼few days and ∼30 days respectively, recurring typically every 10–50 yr. However, linear decays are possible, especially for lower peak luminosities.
- *Variable optical counterpart* that brightens by ∼4–7^m depending on orbital period (a longer period implies a larger and hence brighter secondary star which correspondingly reduces the observed outburst amplitude). Such a large brightness increase at outburst shows that the SXTs are LMXBs, and are *not* similar to Cyg X-1 or the harder Be x-ray transients.
- Lithium has been detected in absorption in five SXTs, and may be created by spallation processes during the intense x-ray outbursts.
- Mini-outbursts sometimes occur within ∼1 yr of the main outburst.
- Superluminal radio jets analogous to those seen in QSOs and other AGN have been seen.
- Residual accretion disks seen in quiescence through the presence of strong, broad Hα emission. Usually exhibiting a double-peaked profile, this implies a disk size ∼0.4–0.7 of the primary ROCHE LOBE. Velocity studies of the emission lines have revealed small phase offsets with respect to that expected if the lines are only associated dynamically with the compact object.
- Galactic distribution of SXTs is consistent with that of population I objects, suggesting that they evolved from massive progenitor stars. There are estimated to be ∼500 in our galaxy.

Black-hole diagnostics?

X-ray spectrum

X-ray properties similar to those of Cyg X-1 are, not surprisingly, frequently used as diagnostics that lead to black-hole candidacy. In addition to a (very stable) power-law component extending to very high energies (∼MeV) which is usually attributed to Comptonization, Cyg X-1 also (occasionally) exhibits a high, soft state which has an additional (multicolor or 'disk') black-body spectrum at a temperature of $kT \sim 1$ keV. Assuming that the inner accretion disk can be represented as a set of rings of decreasing temperature with increasing radius, x-ray spectra suggest that sources suspected (on other grounds) of being black-hole candidates had inner disk radii of $\sim 3r_S$, appropriate for stellar mass black holes (where r_S is the Schwarzschild radius, and $\sim 3r_S$ is the location of the last stable orbit for matter in its vicinity). While the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

continuum spectrum is unaffected by including the effects of GR, they are important for the profiles of spectral lines formed in the inner disk. Only x-ray lines can be formed at such high temperatures, and the effects of GR are believed to have been seen in certain AGN spectra, but not yet in x-ray binaries.

The low-temperature black-body ('soft') component in SXTs has widely varying properties from source to source. Indeed, even though they are classified as SXTs, the two transients GS2023+338 and GRO J0422+32 do not show such components in their bright state (and nor do Cyg X-1 and GX339-4 when in their hard (low) states). At the other extreme, GRO J1655-40 and GRS1915+10 have the highest temperature and most luminous soft component, and are also the only SXTs to display superluminal radio ejections (see the section below on population size and distribution). This has led to the speculative suggestion that the soft component is related to the spin of the black hole, as this property is considered to be important in extragalactic radio jets.

Temporal behavior

A simultaneous analysis of the x-ray spectral and temporal variability is necessary in order to map out these source 'states'. Building on the two-state behavior of Cyg X-1, interesting correlations between their x-ray spectra and temporal variability have been found in the black-hole x-ray binaries. The presence of quasi-periodic oscillations (QPOs, as seen in neutron star systems) also reinforces their interpretation as a property of the inner accretion disk rather than the compact object. The SXT outbursts, when studied from peak to quiescence, cover a very large range in accretion rate onto the compact object, and the x-ray spectral and temporal behavior appears related to the mass accretion rate (table 1).

Furthermore, even faster QPOs (67 Hz, 184 Hz, 300 Hz) have been seen during bright phases of the transients GRS1915 + 105, XTE J1550-564 and GRO J1655-40 respectively. Such short-timescale variability must be associated with the region close to the last stable orbit of the inner accretion disk, and hence has potential importance as a property that arises very close to the black-hole primary. Various models have been proposed to account for the details of this behavior, and all include effects of GR which relate to the mass and spin of the black hole.

Quiescent flux levels

Quiescent SXT x-ray fluxes are much lower than those expected from the mass transfer rate implied by the continuing strong Hα emission, and in particular are lower than in corresponding neutron star systems. This may be due to advection-dominated accretion flows (ADAFs) in which, at low mass transfer rates, the high temperature and low density of gas in the inner disk region combine to produce a cooling time for the gas that exceeds the time to fall onto the compact object. Hence the thermal energy of the gas would be advected into the black hole and 'lost'. While similar flows would occur in neutron star systems, the thermal energy would eventually have to be radiated from the neutron star's solid surface, hence producing an apparently much higher x-ray flux from the same amount of accreted matter.

Mass measurements

Radial velocity curves

Once they reach quiescence SXTs become valuable resources for research into the nature of LMXBs. Optically fainter now by a factor of 100 or more, (they have quiescent magnitudes in the range 17–23), their emission is dominated by the companion star and, while technically challenging, their spectral type, period and radial velocity curve (whose amplitude is the K velocity) can be determined. From the latter two the mass function (equation (1)) can be calculated (table 2), and these represent the absolute minimum values for M_X, since (for all of them) $i < 90^\circ$ and $M_2 > 0$. Changing either of these parameters serves only to *increase* the implied value of M_X. However, to determine the actual value of M_X, additional constraints must be applied, so as to infer values for M_2 and i.

Rotational broadening

In short-period interacting binaries the secondary must be corotating (at velocity v_{rot}) with the primary, and since its size R_2 is given by

$$R_2/a = 0.46(1+q)^{-1/3} \tag{3}$$

then

$$v_{rot}\sin i = \frac{2\pi R_2}{P}\sin i = K_2 \times 0.46\frac{(1+q)^{2/3}}{q} \tag{4}$$

from which q can be derived if v_{rot} is measurable. Typical values are in the range 40–100 km s^{-1}.

Figure 2 shows the summed spectrum of V404 Cyg (Doppler corrected into the secondary's rest frame) and that of a template star, which clearly has much narrower absorption lines. A range of broadening velocities (together with the effects of limb-darkening) are applied to the template for comparison with the target, yielding $v_{rot}\sin i = 39 \pm 1$ km s^{-1}, from which $q = 16.7 \pm 1.4$. Note also that, while the accretion disk around the compact object might be expected to provide some velocity information, the breadth of the Hα line ($\geq$ 1000 km s^{-1}) makes this extremely difficult as the compact object's motion in such high-q systems will be very small (typically $\leq$ 30 km s^{-1}). Nevertheless such motions have been seen, but their interpretation is not straightforward as there is a small phase offset relative to the motion of the companion star.

Having determined q, the only remaining unknown is the orbital inclination i. To date, none of the SXTs is eclipsing (although GRO J1655-40 shows evidence for a grazing eclipse), and so it is the determination of i that leads to the greatest uncertainty in the final mass measurement.

Ellipsoidal modulation

The distorted shape of the secondary (the Roche lobe) produces a so-called *ellipsoidal modulation* as the projected area of the secondary varies around the orbit (figure 3). The form of the Roche lobe is theoretically well determined, and so the observed light curve depends on only two parameters, q and i (note that the modulation will disappear if i=0). Usually q is already determined (previous section), but in practice the ellipsoidal modulation is largely insensitive to q for q >5. This assumes that the secondary is actually filling the Roche lobe, which is reasonable given that mass loss from the secondary is observed via Doppler tomography even during quiescence. Results for i determined in this way are given in table 2 (and the masses in figure 1).

However, the principal uncertainty in this final stage is the problem of any other contaminating light sources, especially the accretion disk, as this will lead to i being underestimated and the compact object mass being overestimated. The disk component has already been measured in the optical (figure 2) and is typically ≤ 10%. To further reduce this effect, ellipsoidal studies

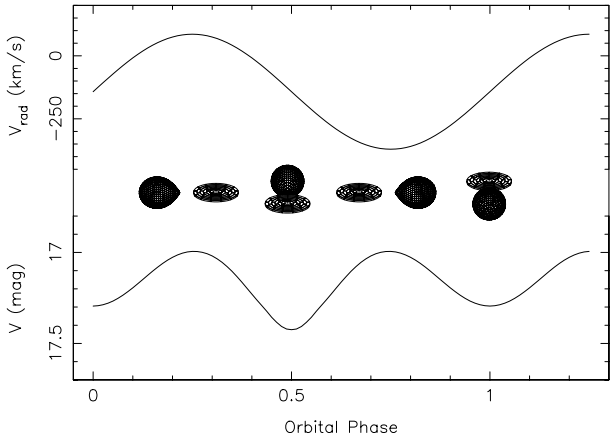

Figure 3. Schematic of the SXT (center) as a function of binary orbital phase, together with (upper) the observed radial velocity of the secondary, and (lower) the ellipsoidal light curve resulting from the distorted (Roche-lobe) shape of the secondary which produces a double-humped modulation.

are performed in the infrared whenever possible (as the disk should be blue in color). Application of this method to the neutron star SXT Cen X-4 yields a value of $1.3M_{\odot}$, in excellent accord with that expected.

The superluminal transients

The discovery, in 1994, of GRS1915 + 105 and GRO J1655-40 brought an entirely new type of behavior to this field. Although other transients were strong radio sources, VLA and VLBI observations showed that these new objects exhibited ejection events that were 'superluminal', the first time that such phenomena had been observed within the Galaxy. Furthermore, both these objects displayed continuing and extremely variable x-ray activity that is totally unlike any of the 'classical' SXTs. Combined with the extremely high interstellar extinction ($A_V \sim 26$) to GRS1915 + 105, dynamical studies of its variable, $K \sim 14$ IR counterpart are currently not possible.

GRO J1655-40 (N Sco 1994) is optically the brightest in quiescence of all the SXTs, with one of the earliest spectral types (mid-F). It also exhibits a high γ velocity which suggests that it might have been formed from a neutron star that had suffered accretion-induced collapse. A subsequent optical rebrightening was found to have begun ∼6 days before the x-rays, indicating an 'outside-in' outburst of the accretion disk. This substantial delay is explained by the inner disk needing to be re-filled before accretion onto the compact object can take place.

The brightness of GRO J1655-40 allows high-quality photometric light curves to be obtained, from which the orbital system parameters can be derived. With such an early spectral type, it has a low mass ratio ($q \sim 3$) which means that the ellipsoidal modulation is sensitive to both q and i (the latter being constrained by the observed grazing eclipse). The normal star appears to be crossing the Hertzsprung gap and about to ascend the giant branch, hence driving the much higher mass transfer rate. Temporary drops in $\dot{M}$ then return it to the transient domain.

Population size and distribution

The locations of ∼90% of SXTs within a galactic longitude range of ±80° implies that they lie within 8 kpc of the galactic centre. However, distance estimates for the current sample suggest they are all < 5 kpc away, and so only ∼10% of the transients occuring in our Galaxy are being detected (owing to a combination of interstellar absorption and sensitivity). Hence the total number of SXTs is ∼200–1000 for a recurrence time range of 10–50 yr. The narrower dispersion in z of the SXTs, compared with neutron star LMXBs, implies that their black holes are not formed by accretion-induced collapse of a neutron star (except possibly GRO J1655-40), but more likely as the end-product of evolution of a very massive progenitor.

Nature of the compact object

With the secure observation of compact objects with masses $\geq 10M_{\odot}$, their interpretation as black holes depends on a knowledge of the maximum mass of a neutron star. This is usually quoted as $3.2M_{\odot}$, but this is based on an assumption of causality (i.e. the sound speed is $<c$) and a knowledge of the density up to which the equation of state is well understood. Relaxing these can increase the limit.

Alternative suggestions for the nature of compact objects include Q stars, where the strong force confines neutrons and protons at densities below nuclear density, leading to a very different equation of state (in which the Q stands for conserved quantity, the baryon number). They can be very compact and hence consistent with the properties of neutron stars. However, the mass of V404 Cyg shows that it cannot be a Q star as it would be inconsistent with current experimental results. In which case, it must be concluded that V404 Cyg and related objects contain black holes.

Blazar

The most variable class of active galaxy. This class of active galaxy includes BL Lac objects and some of the most violently variable quasars, the name 'blazar' deriving from an amalgamation of 'BL Lac' and 'quasar'. According to the unified model for active galaxies, blazar activity is caused by jets of energetic particles flowing out from an active galactic nucleus directly along, or very close to, the observer's line of sight.

See also: active galactic nucleus, active galaxy, astrophysical jets, BL Lacertae objects, quasar.

Blink Comparator

A device, also known as a blink microscope, that enables two photographs or images of a region of sky, obtained at different times, to be compared in such a way that any differences between them are highlighted. The light paths from the two images are arranged so that, when viewed through an eyepiece, they coincide exactly. The two images are then illuminated alternately, switching from one to the other at a frequency of once or twice per second. While features that are identical on both images appear constant and unchanging during the alternating illumination, any features that are present on one plate only appear to blink on and off. Objects that have changed in brightness fluctuate in size, while objects that have changed position appear to jump to and fro in the alternating illumination. The blink comparator, therefore, greatly facilitates the discovery and identification of objects such as variable stars, novae, supernovae, asteroids and comets. Virtual blink comparators are used in digital image analysis systems for CCD data.

Blinking Planetary (NGC 6826)

A planetary nebula in the constellation Cygnus, position RA 19^{h} 44.8^{m}, dec. $+50^{\circ}\,31'$. It is $\frac{1}{2}'$ in diameter and of eighth magnitude, with a tenth-magnitude central star. It gets its name because it tends to vanish when looked at directly through a small telescope, when light from the central star swamps the nebula, and reappears when viewed with averted vision.

Blue Stars at High Galactic Latitudes

When you look up into the sky at night, most of the blue stars you see are hot main-sequence stars associated with the Milky Way, which have rather recently formed from the thin layer of dust and gas in the plane of our Galaxy. Because these stars evolve rapidly, we do not see them at high galactic latitudes, where there is no interstellar material from which they can form. Hence blue stars at high galactic latitudes are rare and must have some other explanation. It was this rareness of the blue stars at high galactic latitude and the lack of a theoretical explanation for them which led Fritz Zwicky to undertake the first survey for such stars, the HZ survey, with the 0.46 m Schmidt telescope on Mt Palomar in 1938. This telescope (and its big brother, the 1.2 m Schmidt) were in fact built to carry out surveys like this one, in order to find objects which were sufficiently interesting to deserve further study with the 5 m Hale reflector.

This and subsequent surveys for blue stars at high galactic latitudes have paid off handsomely, because these stars turn out to tell us not about the early stages of stellar evolution but about the final white dwarf state and the rapid phases of stellar evolution which immediately precede it. In 1965, a new chapter in the story of blue stars at high galactic latitudes was started by Allan Sandage, who predicted that most of the high-latitude blue stars fainter than apparent magnitude 16 in existing surveys were not stars at all but (radio quiet) quasars, the most luminous known objects in the universe. Although later studies showed that this did not actually happen until apparent magnitude 18, the fact remains that the faintest blue 'stars' at high galactic latitudes are one of our most important sources of information on the structure and evolution of the universe. It is also ironic that our primary source of information on the faintest blue stars in our own Galaxy is currently a byproduct of extragalactic research.

In this article we will discuss past and current surveys of blue stars at high galactic latitudes. Deep quasar surveys, which have been recently reviewed by Hartwick and Schade (1990 *Ann. Rev. Astron. Astrophys.* **28** 437), are not included unless it was felt that they have contributed significantly to the study of faint blue stars. What we have learned from further study of the objects discovered in these surveys may be found in the articles on WHITE DWARFS, PG1159 STARS, LARGE HOT SUBDWARFS AND EXTREME HORIZONTAL BRANCH STARS, PLANETARY NEBULAE, RED GIANT STARS, HORIZONTAL BRANCH STARS, RR LYRAE STARS, BLUE STRAGGLERS and LUMINOUS BLUE VARIABLES.

The earliest surveys for blue stars at high galactic latitudes

The Humason Zwicky (HZ) Survey

The HZ survey was carried out using four sets of photographs taken with the 46 cm Palomar Schmidt which covered the Hyades star cluster and a region of about 150 square degrees near the North Galactic Pole. These were taken using emulsion–filter combinations which isolated the spectral regions 3500–5400 Å, 4900–7000 Å, 3500–5200 Å and 3500–3900 Å. The yellow and violet exposures were used to select 48 blue (color index from 0.3 to −0.1), decidedly blue (color index from −0.1 to −0.3), and very blue (color index from −0.3 to −0.6) stars down to apparent photographic magnitude 15. The blue exposures were used to eliminate variable stars. Follow-up spectroscopy at resolutions of 4–8 Å was done by M L Humason with the Mt Wilson 2.5 m reflector, and the results were published by Humason and Zwicky in 1947 (*Astrophys. J.* **105** 85).

The Luyten blue (LB) survey

The search for faint blue stars at high galactic latitudes was greatly extended by Willem J Luyten and his collaborators between 1951 and 1969 using photographic techniques similar to those of the HZ survey. A variety of instruments, including the 1.2 m Palomar Schmidt, was used to search fields all over the sky (most at high galactic latitude), resulting in the discovery of 11 444 stars brighter than apparent magnitude $B = 18$ and bluer than color index $U\text{-}V = -0.2$. Unfortunately, finding charts were not published for many of the fainter stars, and the published coordinates are only accurate to 1 minute of arc, so that much of this material is of statistical interest only. Luyten speeded up the discovery process considerably through the use of a blink microscope, a device which allowed him to view the photographic plates taken in red and blue light in rapid succession through the same eyepiece. Haro's three-image method, which is described in the next section, was also used. The results were published by the Observatory of the University of Minnesota as a series of 52 contributions and monographs by Luyten and his collaborators. Proper motions for many of the blue stars at high galactic latitude have also been published by Luyten.

The Feige survey

This survey was initiated by Jacques Feige in 1956. Red and blue plates taken with the 1.2 m Palomar Schmidt for the Palomar Observatory Sky Survey were blinked for 3600 square degrees at galactic latitudes higher than +55° and for 2400 square degrees for galactic latitudes below −45° and north of declination −15°. 114 stars with apparent photographic magnitude brighter than 14 and color indices less than $B\text{-}V = 0.2$ were identified. This survey, like the HZ survey, proved to be very important in determining the nature of the faint blue stars at high galactic latitude, because the stars were bright enough for follow-up observations to be made with the 5 m and other telescopes (*Astrophys. J.* **128** 267, *Astrophys. J.* **129** 600).

Surveys using Haro's multiple-image technique

The Palomar Haro Luyten (PHL) survey

This survey was carried out in 1958 by G Haro and W J Luyten with the 1.2 m Palomar Schmidt and used a triple exposure through three different filters and a slight offset of the telescope between the exposures to produce a triple image of each star in ultraviolet, blue and visual light on a single photographic plate. 8746 stars bluer than color

Copyright © Nature Publishing Group 2001

Dirac House, Temple Back, Bristol, BS1 6BE, UK

index $U\text{-}V = 0.1$ and brighter than apparent photographic magnitude 19 were identified in a 2400 square degree region near the South Galactic Pole (SGP). Unfortunately, as with the LB survey, the published coordinates are only given to 1 minute of arc, and finding charts were not published, so that much of this material is of statistical use only.

The Tonantzintla (Ton) survey
This survey was carried out at the same time as the PHL survey using the Schmidt telescope at the Tonantzintla Observatory. Areas of 1860 square degrees in the North Galactic Polar Cap and 1050 square degrees in the South Galactic Polar Cap were searched by B Iriarte and E Chavira using the technique described in the previous section. The survey resulted in the detection of 2008 blue stars brighter than photographic magnitude 17 (Iriarte B and Chavira E 1957 *Bol. Obs. Tonantzintla Tacubaya* (16), (17) and (18)).

The Jaidee–Lynga (JL) survey
This was based on dual-image (U and B) plates taken with the 50/65/175 cm Schmidt at Mt Stromlo (Australia). The catalog contains 296 stars in 540 square degrees at high galactic latitudes with $U\text{-}B < -0.6$ and $B < 18$ (1969 *Ark. Astron.* **5** 345).

The PB (Palomar Berger) survey
This was an extension of the PHL survey described above in 2000 square degrees near the SGP (4495 stars) and 450 square degrees near the NGP (4515 stars) (Berger J and Fringant A-M 1984 *AASS* **58** 565).

The KUV (Kiso Ultraviolet) survey
This was based on three-image UGR (ultraviolet, green, red) plates taken with the 105 cm Schmidt at the Kiso Observatory (Japan) (Noguchi *et al* 1980 *Ann. Tokyo Astron. Obs. Ser. 2* **18** 55, Kondo *et al* 1984 *Ann. Tokyo Astron. Obs. Ser. 2* **20** 130). A total of 1186 stars with ultraviolet excesses and $10.0 < G < 18.5$ were identified in a 4000 square degree area, mostly along a belt between the NGP and SGP centered on galactic longitude 180°. Follow-up spectroscopy at a resolution of 12 Å (4500–8200 Å) or 7 Å (4100–7200 Å) is being obtained with the 2.4 and 1.3 m telescopes at the Michigan–Dartmouth–MIT Observatory on Kitt Peak (see Darling G W and Wegner G 1994 *Astron. J.* **108** 2025.

The Usher (US) Survey
This survey is based on Palomar 1.2 m Schmidt plates of 206 square degrees of the sky with galactic latitude greater than 30°. The plates were taken in ultraviolet, blue and visual spectral regions and have isolated 3987 blue stellar objects which are brighter than $B = 18.8$ and bluer than F and G subdwarfs in *B-V* or *U-B*. A spectroscopic follow-up is being done between 3500 and 7000 Å at 14 Å resolution with the Kitt Peak 2.1 m spectrograph. The results to date include the detection of 67 white dwarfs, 36 hot subdwarfs and 30 B-8 and early A-type stars (Usher P D and Mitchell K J 1990 *Astrophys. J.* Suppl. Ser. **74** 885).

The Survey of Rubin, Moore and Bertiau
This survey (Rubin, Moore and Bertiau 1967 *Astron. J.* **72** 59) yielded 233 objects with apparent magnitudes between 15 and 19 and *U-V* bluer than a star of spectral type A0–A5 in a 36 square degree region of the Virgo cluster of galaxies. It is based on a single triple-image plate taken with the Palomar 1.2 m Schmidt.

KPD (Kitt Peak–Downes) survey
This was based on U and B plates taken with the 0.6 m Schmidt at Kitt Peak (Arizona) and covering 1000 square degrees of the Milky Way down to $B = 15.3$. Although this survey was not done at high galactic latitudes, it has been included because the stars selected were similar to those found in the high-latitude surveys and because it contains references to earlier color surveys at low galactic latitudes. The selection of ∼700 objects with $U\text{-}B < -0.5$ was done from visual inspection of overlapping contact films made from the plates. Spectra with 15 Å resolution covering the range 4000–6800 Å were obtained with the Mount Lemmon (Arizona) UCSD–Minnesota 1.5 m telescope (see Downes R A 1986 *Astrophys. J.* Suppl. Ser. **61** 569).

The PG Survey and its southern counterparts

The Palomar Green (PG) survey
This survey was published by R F Green, M Schmidt and J Liebert in 1986 (*Astrophys. J.* Suppl. Ser. **61** 305) and is based on ultraviolet and blue plates obtained with the 46 cm Palomar Schmidt. The plates covered an area of 10 714 square degrees above galactic latitude +30° and 2000.0 declination −10°. The plates were scanned and digitized, and the magnitudes, colors and positions of some 4 million objects then determined by computer. Comparison with photoelectric magnitudes and colors then allowed 1874 objects bluer than color index $U\text{-}B = -0.46$ and brighter than apparent magnitude $B = 17$ to be identified. The positions of all of these objects were published along with timing charts and the results of follow-up photometry and spectroscopy. The latter showed that 6% of the stars were blue horizontal-branch stars, 53% hot subdwarfs, 26% white dwarfs, 5% cataclysmic variables or other binaries and 9% extragalactic.

The Edinburgh–Cape (EC) survey
This is one of two Southern counterparts of the PG survey which are still in progress, and which will cover the 10 000 square degrees of the southern sky with $|b| > 30°$. Ultraviolet and blue photographic plates obtained with the 1.2 m UK Schmidt telescope in Australia are being analyzed by methods similar to those utilized in the PG survey, and the survey is complete to at least the limits of the PG survey, $B = 17$ and $U\text{-}B = -0.4$. Follow-up spectroscopy and photometry are being done at the South African Astronomical Observatory. The results obtained to date (zone 1) include the detection of 101 white dwarfs, 303 hot subwarfs, 75 blue horizontal-branch stars, 62 normal B and A stars, 55 extragalactic, 71 composite and 8 other.

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

The Montreal Cambridge (MC) survey
This is the other counterpart of the PG survey which is still in progress, and it is very similar to the EC survey. It is based on doubly-exposed (U and B) photographic plates taken with the Curtis Schmidt telescope at Cerro Tololo (Chile), and should be complete to $B = 16.5$ and $U\text{-}B = -0.4$ for the 6750 square degrees south of galactic latitude -30° which were not covered by the PG survey (Demers *et al* 1986 *Astron. J.* **92** 878). Follow-up spectroscopy for 251 objects with $U\text{-}B < -0.5$ and brighter than $B = 16.5$ in an 840 square degree region at the pole produced the following results: 54 white dwarfs, 72 hot subdwarfs, 4 cataclysmic variables, 6 blue horizontal branch stars, 16 normal B and A stars, 31 extragalactic objects and 3 other emission-line objects.

Other color surveys

The survey of Braccesi et al
This survey (Braccesi *et al* 1970 *Astron. Astrophys.* **5** 264) is based on u, b, v and i plates taken with the Palomar 1.2 m Schmidt. The catalog contains 175 objects with $u\text{-}b < -0.3$ and $b < 20$ in a 42 square degree field centered at 13 h right ascension and +36° declination. Corrected values for the equatorial coordinates are given in *Astronomy and Astrophysics* (1973 *Astron. Astrophys.* **23** 159). This survey yielded the only published list of optically selected quasars for almost 10 yr. It was extended by Formiggini *et al* (1980 *Astron. Astrophys. Suppl.* **39** 129) using u, b and v plates of the central 1.72 square degrees of this region. The second catalog contains 298 objects with $u\text{-}b < -0.1$ or $u\text{-}v < +0.4$ and $18.0 < b < 20.2$.

The Survey of van den Bergh
This survey (van den Bergh 1966 *Astrophys. J.* **144** 866) yielded 31 objects with $17.5 < B < 20.5$ and $U\text{-}B < -0.5$ in a 4 square degree field in Andromeda. These objects were identified by blinking a well-matched pair of U and B plates taken with the 1.3 m Schmidt telescope of the Karl Schwarzschild Observatory (Germany).

The CCD/Transit Instrument (CTI) blue object survey
This was based on CCD photometry done with the 1.8 m transit instrument at Kitt Peak. This instrument is able to do UBVRI photometry of stars brighter than $V = 20$ in a 8.26 minutes of arc strip at declination +28°. Follow-up spectroscopy for 110 objects is reported by Kirkpatrick and McGraw 1998 *Proc. IAU Colloq.* **114**.

AAT (Anglo-Australian Telescope) survey
This survey (Boyle B J *et al* 1990 *Mon. Not. R. Astron. Soc.* **243** 1) used UK Schmidt U and J plates for 34 0.35 square degree fields at high galactic latitude. The catalog contains 1400 stars with $16.9 < B < 20.9$ and $U\text{-}B < -0.35$ and differs from its forerunners in that 12–15 Å resolution spectroscopy has been obtained with the AAT for all of the stars, and the results are included in the catalog.

Cerro El Roble (CT) survey
This survey is based on ultraviolet and blue photographic plates taken with the 0.7/1.0 m Maksutov telescope at Cerro El Roble (Chile). Blinking of these plates has produced a catalog of 373 stellar objects with $U\text{-}B < -0.5$ down to $B = 20$ in a 44 square degree region near the south galactic pole (Campusano L E and Torres C 1983 *Astron. J.* **88** 1304).

HBQS (Homogeneous Bright QSO) survey
In this survey (Cristiani *et al* 1995 *Astron. Astrophys. Suppl. Ser.* **112** 347) objects with ultraviolet excesses and $B < 19$ were identified on ESO and UK Schmidt UBVRI plates in 153 square degrees near the SGP. 285 QSOs and a comparable number of blue stellar objects were then identified from 10–30 Å resolution ESO spectra of the objects with ultraviolet excesses. This survey is to be extended to entire south galactic polar cap ($b < -60^\circ$), and has been used to make a new determination of the luminosity function of hot white dwarfs.

Objective-prism surveys

The survey of Slettebak and Stock
This was done with the Hamburg 80 cm Schmidt and covered roughly 750 square degrees centered at the NGP. The spectroscopic dispersion was 590 Å mm^{-1} at H gamma, and the limiting magnitude was between $B = 12$ and 14. The survey yielded 601 stars of spectral type F2 and earlier (1959 *Astron. Abh. Hamburg Sternwarte* **5** (5)).

The Slettebak and Brundage (SB) survey
This was done with the Schmidt telescope at Cerro Tololo (Chile) and covered 840 square degrees centered at the SGP. The spectroscopic dispersion was 580 Å mm^{-1} at H gamma, and the limiting magnitude was between $B = 14$ and 15. The survey yielded 957 stars of spectral type F0 and earlier, and the results are given in the *Astronomical Journal* (1971 *Astron. J.* **76** 338).

A G D Philip and collaborators
These researchers have identified 1108 stars of spectral type A7 and earlier on objective-prism plates of various regions at high galactic latitudes taken with the Schmidt telescopes at Tonantzintla (Mexico), Cerro Tololo (Chile) and the Warner and Swasey Observatory (Ohio). The spectra cover the blue region at dispersions ranging from 280 to 580 Å mm^{-1} at H gamma down to $B = 13$. The results are published in the Boletin de los Observatorios Tonantzintla y Tacubaya.

The FHB surveys
These high-latitude surveys were carried out with the Schmidt telescopes at Cerro Tololo (Chile) and Kitt Peak (Arizona). They employed an ingenious technique which allowed early-type stars to be identified to apparent magnitude $B = 15$ at a dispersion of 280 Å mm^{-1} at H gamma. This technique employed a blocking filter which allowed only light of the 150 Å spectral region

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

centered on Ca II H and K lines to reach the photographic plate, thus eliminating 85% of the sky background, which limits the exposures. Stars with the Ca II K line missing (FHB/AB) have effective temperatures greater than 10 000 K, and those where it is weak (FHB/A) are primarily blue horizontal branch stars at high galactic latitudes. More than 11 500 FHB/A stars have been identified to date by visual scanning of the plates (Beers *et al* 1992 *Astron. J.* **103** 267).

The LS (Luminous Stars) surveys
These were objective-prism surveys (Stephenson C B and Sanduleak N 1970 *Publ. Warner Swasey Obs.* **1** 1, Drilling J S and Bergeron L E 1995 *Proc. Astron. Soc. Pac.* **107** 846) carried out with Schmidt telescopes at Hamburg, Cleveland and Cerro Tololo, at 280–580 Å mm^{-1} at H gamma. These surveys cover the entire Milky Way plus $|b| < 30^\circ$ for $300^\circ < l < 60^\circ$. These surveys have been included because follow-up spectroscopy has yielded many of the same kinds of objects found at high latitudes and because they contain references to earlier low-latitude objective-prism surveys.

The Case Low-Dispersion Northern Sky survey
This is an objective-prism survey in progress which will cover the 8000 square degrees of the northern sky with $b > 30$ using the Case 61 cm Schmidt at Kitt Peak. The photographic spectra have a dispersion of 1360 Å mm^{-1} at H gamma and cover the spectral region from 3300 to 5350 Å down to photographic magnitude $B = 15$–18. Visual scanning of the plates has turned up 1579 blue or emission line galaxies, 1136 unresolved blue or emission line objects, 465 known or suspected blue stars, 1110 A and F stars, and 132 faint carbon and suspected late M halo giants at the time of this writing, as well as a number of probable H II regions in other galaxies. The results are being published in the *Astrophysical Journal Supplement*.

The Hamburg Quasar Survey (HQS)
This is similar to the Case survey, but using the Hamburg 80 cm Schmidt telescope at Calar Alto (Spain). The entire northern sky will be covered for $|b| > 19^\circ$ down to $B = 18.5$. The spectra cover the wavelength range 3400 to 5400 Å and have a dispersion of 1390 Å mm^{-1} at H gamma. The plates are being scanned and analyzed digitally, and this is the first objective-prism survey to utilize an automatic selection of objects rather than visual scanning (Hagen *et al* 1995 *Astron. Astrophys. Suppl. Ser.* **111** 195).

The Hamburg/ESO survey (HES)
This is the southern counterpart of the HQS survey described in the previous section, based on objective-prism plates taken with the ESO 1 m Schmidt at a dispersion of 450 Å mm^{-1} at H gamma, which reach down to $B = 17.5$. Results for the first 1000 square degrees of coverage are reported by Wisotzki *et al* (1996 *Astron. Astrophys. Suppl. Ser.* **115** 227).

The First Byurakan survey
This survey was begun by B E Markarian to search for active galactic nuclei. More than 2000 objective-prism plates were taken with the 1 m Schmidt telescope of the Byurakan Observatory (Armenia), covering the entire northern sky and that part of the southern sky with declination $> -15^\circ$ and $b > 15^\circ$. The spectra cover the range from 3400 to 6900 Å (with a gap near 5300 Å) at a dispersion of 1800 Å mm^{-1} at H gamma. Scanning of 438 of these plates by H V Abrahamian, A M Mickaelian and others has yielded 1103 blue stellar objects. Follow-up spectroscopy with the Byurakan 2.6 m telescope indicates the following composition for the sample: 56% hot subdwarfs, 16% white dwarfs, 8% main sequence OB and HBB stars, 3% cataclysmic variables and other binaries, 4% extragalactic and 13% other.

The survey of Rodgers, Roberts, and Walker
In this survey (Rodgers, Roberts and Walker 1993 *Astron. J.* **106** 591) objective-prism plates were obtained in two 70 square degree regions at $l = 90^\circ$ and 270°, $b = -45^\circ$ with the Anglo-Australian Schmidt. The spectra have a dispersion of 600 Å mm^{-1} at H gamma and 436 stars with spectral type F and earlier and $V < 16$ were classified and cataloged.

The future of surveys for blue stars at high galactic latitudes

The era of color surveys for blue stars at high galactic latitudes is probably nearing an end. The SLOAN DIGITAL SKY SURVEY (SDSS) is a good example of what lies in the future. The SDSS will employ a 2.5 m telescope and CCD detectors to obtain accurate five-color broad-band photometry covering the entire visible and near-infrared spectrum for all stars brighter than apparent magnitude $g' = 23$ in a 10 000 square degree area centered on the NGP. Photometric and positional information for both the stars and extended sources will be stored in a gigantic database which astronomers will be able to access remotely. Each astronomer will therefore be able to make his or her own survey by computer, using the SDSS database rather than the real sky. It is, in fact, already possible to do this using one of the three existing independent digitizations of the original Palomar Observatory Sky Survey. The catalog obtained by scanning and digitizing the original plates of the Palomar Observatory Sky Survey with $|b| > 19^\circ$ and $\delta > -31^\circ$ using the automatic plate scanner at the University of Minnesota is available over the internet at http://isis.spa.umn.edu.

Objective prism surveys are a different story, but the scanning and digitization of objective prism plates have already been successfully used in the Hamburg quasar surveys to make at least an initial classification of objective-prism spectra, and it is probably just a matter of time before large-scale objective-prism surveys are done with digital detectors.

Blue Stragglers

The most flagrant blue stragglers are stars that cannot be older than one or two billion years, lurking in the cores of 13 billion year-old GLOBULAR CLUSTERS. The origin(s) and evolution of these puzzling objects are the central challenges confronting researchers in this field.

ALLAN SANDAGE was the first to note the existence of blue straggler stars (BSS) when he constructed a deep color–magnitude diagram for the globular cluster M3 as part of his PhD thesis in 1952. This classic diagram (reproduced in figure 1) demonstrated beyond doubt that at least two dozen stars in the cluster lie near the hydrogen-burning main sequence, but that they are hotter and more luminous than stars at the main sequence turnoff. Only two explanations seemed possible: either these stars were considerably younger and more massive than all other cluster stars, or the theory of STELLAR EVOLUTION was seriously in error. As many lines of evidence strongly supported stellar evolution theory (then and now), the question that emerged was: how can ancient STAR CLUSTERS, devoid of star-forming gas, construct new stars billions of years after STAR FORMATION in the cluster ceased?

Ages of stars in clusters

The ages of star clusters containing hundreds to millions of members can be gauged with an accuracy approaching 15%. This is because individual stars change two of their observable properties, color and brightness, in a very predictable fashion (correlated with age) as they finish fusing their core hydrogen into helium. Such *turnoff* stars rapidly become redder and brighter as they swell in size, eventually ballooning to become red giants. Determining the age of a star cluster is thus quite simple: it's just the age of the most luminous star in the cluster which is still at the turnoff point on the hydrogen-fusing main sequence. Comparing the intrinsic brightnesses and colors of computer models of turnoff stars with direct measurements of those same quantities for real cluster stars directly yields stellar and cluster ages. This methodology leads to an age of about 13 billion years for the globular cluster M3 (and all the other Galactic globular clusters); and an upper limit of about two billion years for the brightest cluster BSS.

BSS in color–magnitude diagrams

Catalogs of BSS in clusters now contain over a thousand members. It is clear that BSS do not simply lie along the extensions of cluster main sequences, but are also found considerably redward of the zero-age main sequence. This is an important observational constraint that must be explained by any viable BSS theory.

Location

Prior to the launch of the Hubble Space Telescope, BSS were known to exist in only a handful of globular clusters. Every globular cluster whose core has been searched by Hubble in the past decade displays tens to hundreds of BSS (figure 2).

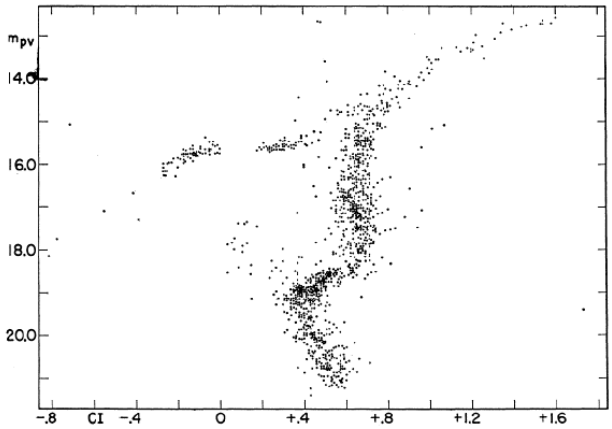

Figure 1. Reproduction of the color–magnitude diagram of M3 presented by A Sandage in 1953 *Astron. J.* **58** 61. The blue stragglers are the stars near $0 < \mathrm{CI} < 0.3$ and $17 < m < 19$.

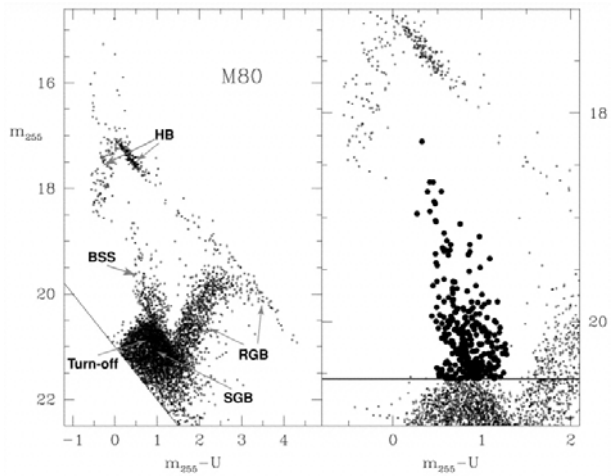

Figure 2. Color–magnitude diagram of M80 from Ferraro *et al* 1999 *Astrophys. J.* **522** 983. 'BSS' marks the blue stragglers in the left hand panel—they are the heavy dots in the magnified section on the right.

These stars are invariably more strongly centrally concentrated than cluster RED GIANTS or HORIZONTAL-BRANCH STARS (figure 3), while being virtually absent from the peripheries of almost all clusters (M3 is a notable exception).

The ubiquitous central concentration of BSS in globular clusters is probably due to equipartition of energy amongst the cluster stars. In this process the kinetic energy of all stars ($\frac{1}{2}Mv^2$) is equalized by gravitational interactions between stars in the cluster.

The more massive stars (larger M) thus acquire smaller velocities v and tend to *sink* towards cluster centers. The centrally concentrated BSS are thus expected to be significantly more massive than any other population

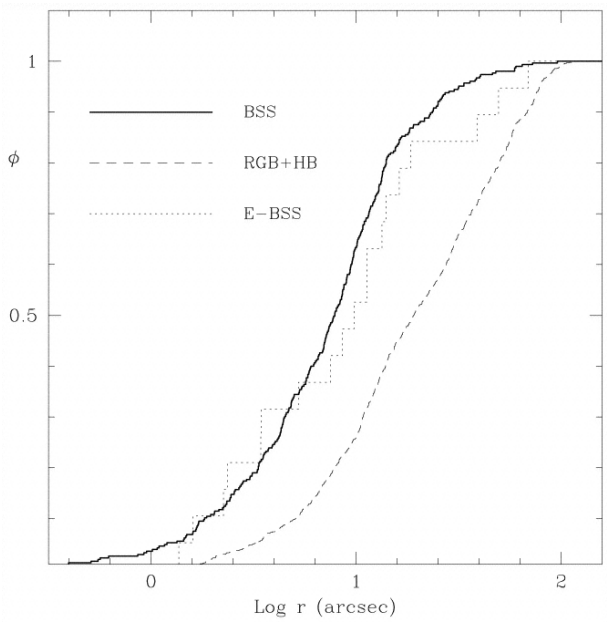

Figure 3. Cumulative radial distribution of BSS (heavy solid line) and horizontal branch and red giant branch stars (dashed line). As presented in Ferraro *et al* 1999 *Astrophys. J.* **522** 983.

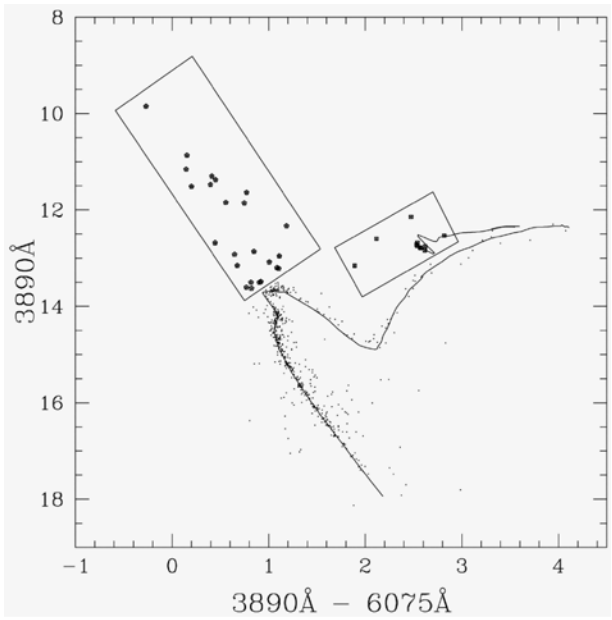

Figure 4. Color–magnitude diagram of M67. BSS are large dots in the box on the left. As presented in Deng *et al* 1999 *Astrophys. J.* **524** 824.

of cluster stars.

This is consistent with BSS's relatively high luminosities and blue colors. Strong observational confirmation has come from direct spectrographic measurement of the radius and surface gravity of the second-brightest BSS in the globular cluster 47 Tucanae. This measurement yielded a mass 1.7 times that of the Sun, or twice the mass of stars at the cluster turnoff. Other mass estimates (from an eclipsing system and from pulsation masses) are consistent with masses greater than the turnoff, but are not yet precise enough to be considered definitive.

BSS are also commonly observed in open clusters (figure 4), in the field as early-type high velocity stars, in the dwarf spheroidal galaxy companions to the Milky Way (figure 5) and in globular clusters of the Magellanic Clouds (figure 6).

Rotation

If BSS are produced by stellar mergers (including off-center collisions), they should be rapidly rotating, at least initially. Observations of a handful of BSS in old open clusters have shown most to be moderate rotators (typically 50 km s^{-1}). It has been suggested that newly formed BSS might be swollen, with large convective envelopes able to carry away angular momentum. While this may occur, much larger observational samples are needed before the oft-quoted observational result of *slow* cluster BSS rotation should be taken as seriously as it is now. In contrast, the direct measurement of $v \sin i = 155$ km s^{-1} for the second brightest BSS in the core of 47 Tuc emphasizes that at least some cluster BSS are rapid rotators.

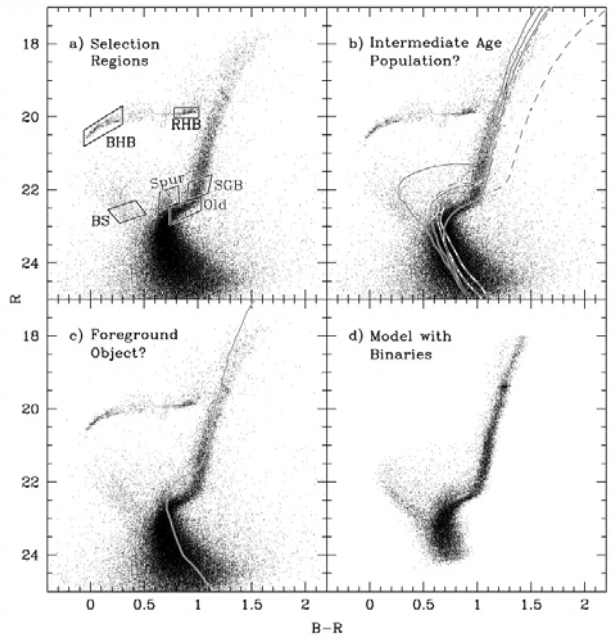

Figure 5. Color–magnitude diagrams of the inner and outer regions of the Sculptor dwarf spheroidal galaxy showing the presence of BSS. As presented in Hurley-Keller *et al* 1999 *Astrophys. J. Lett.* **523** L25.

Lithium abundances

Lithium is a fragile nucleus, destroyed by proton capture at temperatures exceeding 2 million degrees. Large-scale mixing destroys surface lithium, so its presence (or

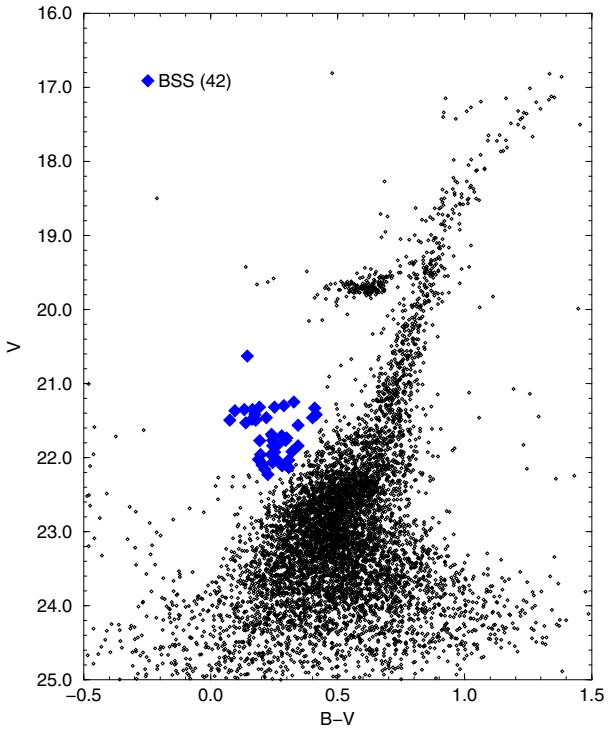

Figure 6. Color–magnitude diagram of the Small Magellanic Cloud cluster NGC 121. BSS are marked with the larger symbols. As presented in Shara *et al* 1998 *Astrophys. J.* **508** 570.

absence) in the spectrum of a star is a sensitive indicator of the temperature history of surface material.

Seven blue stragglers in the old open cluster M67 have been found to be depleted of lithium with respect to normal field main sequence stars of similar spectral types by at least a factor of 30. This is consistent with extensive mixing of internal material to the stellar surface during the production of those cluster BSS. A number of high velocity, but Population I abundance stars were also found to have low Li abundance, suggesting that they, too, are BSS.

Pulsating BSS

The low luminosity extension of the Cepheid instability strip overlaps the location of BSS in globular clusters. These stars obey period–luminosity–color relations analogous to those of classical Cepheids. The mass of a pulsating variable can be determined from the relation

$$M \sim \frac{Q^2 L^{1.5}}{P^2 T^6}$$

where Q is the star's pulsation constant (for a given mode), P is the pulsation period for that mode, L is the star's luminosity and T is its effective temperature. There is, unfortunately, no way known to unambiguously determine the pulsation mode for most pulsating variables. The strong sensitivity to adopted values of luminosity, and especially to effective temperature, can lead to significant uncertainties in the calculated masses. This can be somewhat improved by calculating the mass ratios of pulsating BSS to those of RR LYRAE STARS in the same clusters. Uncertainties in the cluster distances remain, but the resulting BSS masses are typically twice those of RR Lyrae stars. It is something of a puzzle that many BSS in the instability strip do not pulsate. Rapid rotation inhibits pulsation, so non-pulsating BSS may be rapid rotators.

BSS in contact binaries

Contact binaries (CB) have been suggested as the progenitors of at least some BSS. CB are, by far, the most common type of short-period eclipsing systems in the solar neighborhood. The components of these short-period binaries are in physical contact with their Roche equipotential lobes. The components are also in physical contact near the inner Lagrangian point located between the stars.

CB are the most common ECLIPSING BINARIES in open and globular clusters, where the advent of CCD detectors has led to the discovery of significant numbers of these stars. Surveys are still far from complete because the discovery probability plummets for systems with orbital periods longer than a day or two.

If CB give rise to BSS then one would expect the ratio of the number of BSS that are CB to the total number of BSS in a cluster to simply equal the ratio of the CB and BSS lifetimes. Unfortunately the lifetimes of CB are not well determined, so this elegantly simple comparison cannot be made with confidence.

This brief summary of the observed properties of BSS forms a set of constraints on BSS theories. Models that seek to explain the origin and nature of BSS must explain the range of environments in which they are found, their high masses, low lithium abundances, and (possibly) high rotation rates.

Blue straggler models and predictions

Ten models (and at least as many variants) have been proposed to explain the origin of blue stragglers; six involve single stars while four can operate only in binaries. Only the binary mechanisms (see below) are now considered viable. These have been summarized by Mario Livio as:

S1 Multiple bursts of star formation

S2 Prolonged lifetime due to internal mixing

S3 Main sequence stars managing to avoid mass loss

S4 Stars that accreted gas from the ISM or the intracluster medium

S5 Evolved stars that returned to the main sequence

S6 Young field stars captured by clusters

B1 Mass increase as a result of mass transfer in a close binary

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

B2 Coalesced contact binaries

B3 Coalesced common envelope binaries

B4 Mergers as a result of physical stellar collisions.

Observations (especially the low lithium abundance) and theory are able to rule out the single-star mechanisms with a high degree of confidence. The binary mechanisms are all much harder to discount, and workers in the field now suggest that all four scenarios may be at work, though at different rates in different places. The thorniest problems facing the binary hypotheses (B1) and (B2) are as follows.

B1. If mass transfer in binaries produces all BSS then all BSS should be in binaries. Radial velocity studies show that while some BSS are in binaries, intensive monitoring over periods of years conclusively shows that others are not in binaries close enough to lead to mass transfer.

B2. Coalescence of a contact binary to form a BSS is potentially problematic because of the existence of BSS with masses larger than twice the host cluster turnoff mass. This might be a preferred formation route in low density clusters where no other viable mechanism (collisions in particular) works.

Common envelope evolution (**B3**) might be able to generate the most massive BSS by permitting the swallowing of a more distant companion or companions during the expanded envelope phase.

Long thought to be so rare that they could be ignored, physical collisions (**B4**) (and very close passages) are now known to be commonplace and very important in dense star clusters. Hundreds of physical collisions must occur in the cores of most globular clusters during a Hubble time. This is mostly due to the effect of gravitational focusing. Stars move with velocities (v) of at most 10–20 km s^{-1} in globular clusters, much less than the escape speed of a main sequence star. The effective cross section σ_{ss} of two cluster stars of masses m_1 and m_2 and radii r_1 and r_2 is

$$\sigma_{ss} = \pi(r_1 + r_2)^2 \left(1 + \frac{2G(m_1 + m_2)}{(r_1 + r_2)v^2}\right)$$

which can be 10 000 times larger than the geometrical cross sections because of the slow passages of two stars by each other. This magnification is even more remarkable for binaries. The effective cross section of a binary passing close to a single star (or another binary) is approximately the square of the semimajor axis; this can be millions of times the stars' geometrical cross sections.

Mutually induced gravitational distortions can lead to dissipation of orbital energy and capture of an initially parabolic pair of single or binary stars into a highly elliptical orbit. Subsequent periastron passages can dissipate more energy, leading eventually to very close binaries and/or physical collisions.

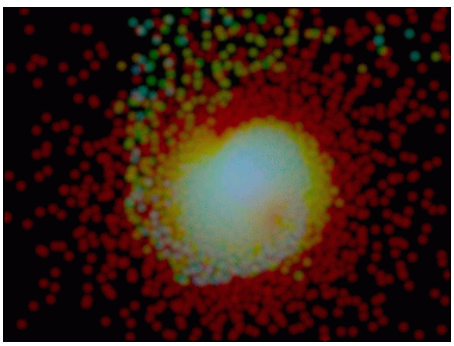
(b)



(c)

Figure 7. Example of a simulation of an off-axis collision between two main sequence stars of different mass. From J E Barnes' website http://www.ifa.hawaii.edu/faculty/barnes/stars.html

Physical collisions

Even in the cores of the most dense Galactic globular clusters the interval between physical stellar collisions must be at least 10^5 years (otherwise every star near the cluster center would already have experienced a collision). It is very unlikely that the tools needed to directly image a stellar collision (far outside the Galaxy) will be developed during the next two or three decades (though gravity wave detectors might detect them indirectly in just a few years). For the present, studies of stellar collisions are of necessity confined to numerical simulations on computers.

When main sequence stars undergoing a nearly head-

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

on collision are of comparable density and size the initially spherical masses increasingly overlap as they compress and distort each other into nearly half-moon shapes. Temperatures and densities never become high enough to ignite significant thermonuclear burning outside the stellar cores. A few per cent of the total mass of two colliding main sequence stars is ejected perpendicular to the direction of stellar motion, but then mixing and overlap take over. Within a few dynamical times (hours) the two incoming stars are merged together into a single, new star almost as massive as the sum of its progenitors' masses.

Real collisions will almost always be off-center, involving rotating stars of unequal mass. The predicted degree of mixing that ensues in any collision is quite dependent on the density profiles, impact parameter and initial relative velocities of the colliding stars, but at least some surface mixing seems hard to avoid. Very rapidly spinning stars surrounded by massive disks have been suggested by some simulations. Other models predict that the denser of two colliding stars' cores can penetrate to the core of the less dense (and more massive) star (see figure 7). This is the fundamental reason why the apparent age (from its position in a cluster color–magnitude diagram) of a coalesced star is predicted to *not* be synchronized with the ages of all the non-coalesced stars in a cluster core. Mixing of surface and core layers during a collision may produce a coalesced star having a higher central hydrogen content than either of the stars which formed it.

In effect, the core-hydrogen-rich coalesced star has had its clock reset by the collision. Despite the uncertainties and approximations used, the detailed numerical simulations of stellar coalescence through collisions give this process a credence that the other binary mechanisms are hard pressed to match.

Cluster models with collisions

Two very recent theoretical approaches have greatly increased the realism of coalescing star simulations. In one work, simple representations of dense star cluster dynamics and detailed binary–single star encounter simulations were combined to produce cross sections and rates for a variety of collisions. The collision outcomes were calculated with smoothed-particle hydrodynamics (SPH) simulations of realistic star models, then followed in detail with a stellar evolution code. Some of the predicted distributions in theoretical cluster color–magnitude diagrams mimic observed distributions with remarkable fidelity (figure 8).

The study tested the sensitivity of the predicted color–magnitude distributions to the stellar evolution tracks, binary mass function, binary period distribution and current mass function. The first two parameters are much more important than the latter two. Fully mixed stars produce BSS distributions that start on and always remain close to the Zero Age Main Sequence. Partially mixed configurations (in accord with the SPH simulations noted above) produce color–magnitude distributions that are more spread out in color than the fully mixed distributions, in much better accord with the observations.

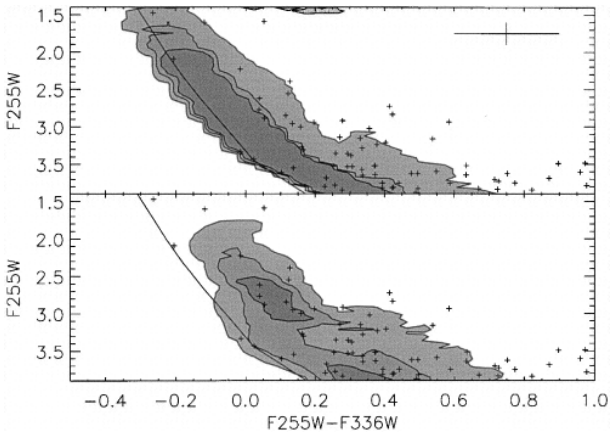

Figure 8. Theoretical color–magnitude diagrams comparing the effects of using different evolutionary tracks for the blue stragglers. As presented by Sills A and Bailyn C 1999 *Astrophys. J.* **513** 428.

Binary star cross sections are much larger than those of single stars, so binary–single collisions overwhelm single–single collisions for even a modest binary frequency. The future inclusion of binary–binary collisions and coalescences may explain the few, most luminous BSS not reasonably explained by the simulations.

A second approach uses detailed N-body simulations coupled with simple prescriptions for stellar evolution and physical collisions. The initial conditions were chosen to mimic R136, the massive and compact star cluster at the center of the 30 Doradus complex in the Large Magellanic Cloud. Simulations show that the dynamical evolution of the cluster is tightly linked to the evolution of the most massive stars. A single very massive star ($>100M_{\odot}$) is found to grow steadily through mergers with other stars in less than 3–4 Myr. This object is usually found in a binary system very close to the cluster center, and it is *rejuvenated* by each successive collision. It should appear as a BSS in the cluster color–magnitude diagram. Strong stellar winds slow the runaway process, but even large mass loss rates do not prevent the growth of very massive BSS.

The two approaches described above clearly must be merged to eventually produce a realistic scenario capable of being tested in detail against observed BSS in star clusters. Spurred largely by the Hubble Space Telescope, BSS research is now a rapidly developing field driven by the synergy between theory, simulations and observations.

Bibliography

Half a century ago the infant field of stellar evolution, coupled with state-of-the-art observations of globular clusters, was used to demonstrate the extraordinarily ancient nature of these objects. Allan Sandage was then a PhD student at Caltech, and his beautiful dataset on the cluster M3 clearly showed, for the first time, blue

stragglers. This discovery paper (Sandage A R 1953 *Astron. J.* **58** 61) reads as well today as then.

A monograph entitled *Blue Stragglers* (ASP Conference Series 53: ed R Saffer 1992) contains a dozen excellent overviews of all aspects of the subject, as do two more recent reviews (Stryker L 1993 *Publ. Astron. Soc. Pacific* **105** 1081, Bailyn C 1994 *Science* **263** 44). A beautiful computer simulation movie of a stellar collision may be viewed online at http://www.ifa.hawaii.edu/faculty/barnes/stars.html

Recent sophisticated treatments of N-body simulations, including the effects of mergers, are reported in Portegies Zwart S *et al* 1999 *Astron. Astrophys.* **348** 117. Simulations of the detailed evolution of merged stars appear in Sills A and Bailyn C 1999 *Astrophys. J.* **513** 428. These complementary approaches provide the most convincing explanations of mergers and BSS in dense star clusters to date.

Boötes

(the Herdsman; abbrev. Boo, gen. Boötis; area 907 sq. deg.) A northern constellation that lies between Canes Venatici and Serpens Caput, and culminates at midnight in late April. The origin of the constellation figure is uncertain, though it dates back at least to ancient Greece, where it was identified with Arcas, who was conceived when his mother, Callisto, fell victim to Zeus's passion and whom Zeus placed alongside Callisto (who is represented by the neighboring constellation of Ursa Major) in the sky. The name Boötes may come from a Greek word meaning 'clamorous' or 'noisy', possibly from the herdsman's shouts to his dogs (now represented by the neighboring constellation of Canes Venatici). In some early celestial charts Boötes is shown in pursuit of a bear (the constellation of Ursa Major). The brightest stars of Boötes were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large constellation, Boötes is easily found by virtue of α Boötis (Arcturus), which at magnitude -0.1 is the fourth brightest star in the sky and lies on a continuation of the line joining the stars ε, ζ and η Ursa Majoris, in the tail of the Great Bear. Other bright stars include ε Boötis (Izar or Pulcherrima), a close binary with yellow (K0) and blue (A2) components, magnitudes 2.7 and 4.8, separation $3''$, η Boötis (Muphrid), magnitude 2.7, and γ Boötis (Seginus), magnitude 3.1. There are five other stars of magnitude 4.0 or brighter. Another interesting binary is ξ Boötis, which has yellow (G8) and orange (K4) components, magnitudes 4.8 and 7.1, separation $7''$.

There are no bright star clusters, nebulae or galaxies in Boötes.

The Quadrantid meteor shower appears to radiate from the northern part of Boötes, which contains the former constellation of Quadrans Muralis, after which it is named.

Bode, Johann Elert (1747–1826)

Astronomer, born in Hamburg, Germany, director of the Berlin Observatory. He drew attention to a relation among the distances of the planets from the Sun that had been discovered by JOHANN TITIUS. The law is sometimes known as the *Titius–Bode law*, but usually just as *Bode's law*. The law starts with the sequence 0, 3, 6, 12, 24. . . , adds 4 and divides by 10 to obtain 0.4, 0.7, 1.0, 1.6. 2.8. . . , which is a good approximation for the distances from the Sun of all the planets in units of the astronomical unit. The law has entries for the then undiscovered asteroids and Uranus, but fails at Neptune. The explanation for the law (if there is one) remains unknown. Bode discovered M81 (known as Bode's nebula), M82, M53, M92 and M64, and published in 1779 *A Complete Catalogue of Hitherto Observed Nebulous Stars and Star Clusters*, which, unfortunately, contains in its 75 entries many non-existent objects and uninteresting asterisms.

Bode's Law

A numerical sequence which is roughly in proportion to the distances of the major planets from the Sun. It is named after Johann Bode, who announced it in 1772; it is more properly referred to as the *Titius–Bode law*, as it was first put forward by Johann Titius six years previously. The sequence is formed by taking 0 and 3, doubling 3 to give 6, doubling 6 to give 12, and so on, then adding 4 to each term to give 4, 7, 10, 16, . . ., and finally dividing each term by 10. The formula $\frac{3}{10}(2^n - 1) + 4$, $n = 0, 1, 2, \ldots$ yields each term. The correspondence with the distances of the planets (to the nearest 0.1 AU) is given in the table.

Planet	Bode's law distance (AU)	Actual distance (AU)
Mercury	0.4	0.4
Venus	0.7	0.7
Earth	1.0	1.0
Mars	1.6	1.5
Ceres	2.8	2.8
Jupiter	5.2	5.2
Saturn	10.0	9.5
Uranus	19.6	19.2
Neptune	38.8	30.1
Pluto	77.2	39.5

Bode made his announcement before the asteroids or the planets beyond Saturn had been discovered. The relationship remained something of a curiosity until the discovery of Uranus in 1781. Once the new planet's distance from the Sun was established and seen to fit the numerical pattern, astronomers considered more seriously the apparent gap between Mars and Jupiter, and were prompted to begin searching for a missing planet. The first asteroid to be discovered, Ceres, in 1801, was by no means a major planet, but it did orbit at the predicted distance from the Sun. This predictive power gave the Titius–Bode relationship the status of a 'law', though it was transgressed by the subsequent discoveries of Neptune and Pluto at distances that broke the pattern.

Bok, Bart Jan (1906–83)

Dutch astronomer, worked at Harvard and directed the Mount Stromlo Observatory (near Canberra, Australia). Studied the structure and evolution of star clusters and the Galaxy, mapping the spiral arms of the Milky Way, especially the Carina region, and the Magellanic Clouds. Bok realized that the sky quality at Mount Stromlo was deteriorating with the growth of Canberra and chose Siding Spring Mountain near Coonabarabran as the new station for the Australia's main optical observatory, eventually the site for the Anglo-Australian 150 in telescope. Bok initiated radioastronomy at Harvard and promoted it elsewhere. His investigations of interstellar gas and dust led to studies of star formation, and he became known for his work on small dark nebulae now called *Bok globules*.

Bolide

A bright meteor—a fireball—that produces audible sounds. Sonic effects are generated once the incoming meteoroid has penetrated to an altitude of around 30 km, and so will be heard some minutes after the fireball is seen. An initial sonic boom indicates that the meteoroid has exploded. If large enough, the resulting fragments will create their own sonic booms, and an object that undergoes multiple fragmentation may generate a continuous, thunder-like rumbling. The fragments of a meteoroid that produces a bolide may well survive their atmospheric passage to fall as meteorites. The Allende meteorite, which underwent multiple fragmentation, was preceded by a bolide.

Bond, William Cranch (1789–1859) and Bond, George Phillips (1825–65)

Instrument-maker and astronomer, born in Portland, ME. Massachusetts businessman, first (unpaid) director of the Harvard College Observatory, with its magnificent 15 in telescope. He identified Saturn's innermost Crêpe Ring. Independently of William Lassell, he discovered the seventh satellite of Saturn, Hyperion, with his son George Bond (the observatory's second director). George correctly realized that Saturn's rings could not be solid, as shown by JAMES CLERK MAXWELL.

BOOMERANG

This is an acronym for 'Balloon Observations of Millimetric Extragalactic Radiation and Geophysics', an experiment which produced an image of the farthest region of the universe observable today. This region is about 15 billion light-years away, and the structures visible in the image existed about 15 billion yr ago. They represent the first stage of the process of formation of the large-scale structures in our universe. They are visible because their presence slightly modifies the otherwise isotropic COSMIC MICROWAVE BACKGROUND (CMB). This radiation, produced in the very early universe, is observable today in the microwaves as a blackbody with a temperature of 2.73 K. The photons of the CMB, generated soon after the big bang (see BIG BANG THEORY), were continuously scattered by free electrons until the expanding universe cooled below 3000 K.

At that point, called 'recombination', about 300000 yr after the big bang and about 15 billion yr ago, the universe became neutral (hydrogen atoms formed from free electrons and protons) and transparent. Since then, the CMB photons have been free to propagate without interacting with matter anymore. They thus arrive at our telescopes carrying the imprint of all the protostructures present at the recombination epoch. Very sensitive telescopes are needed to detect the small (10–100 parts per million, ppm) perturbations in the CMB, usually called 'anisotropies', produced by these protostructures. The BOOMERANG experiment (figure 1) was flown by means of a stratospheric balloon, at an altitude of 37 km, in order to observe above the bulk of the Earth's microwave-absorbing atmosphere. It was launched from Antarctica, and remained at float from 29 December 1998 to 8 January 1999. It observed about 4% of the sky, in a high Galactic latitude region centered at RA=7.5h, dec=-45°. The experiment had 16 independent measurement channels sensitive to four wavelengths: 3.0, 2.0, 0.12 and 0.73 mm.

The detectors were 'spider web' semiconductor bolometers, cooled by a ^{3}He cryogenic system at 0.3 K to reduce their noise. The experiment used an off-axis telescope with an aluminum primary mirror, 1.3 m in diameter. The angular resolution obtained in this way was 18, 10, 14 and 13 arcmin respectively for the four bands. A subsection of the map produced at the wavelength of 2 mm is visible in figure 2. The false colors (from black to yellow) represent anisotropies of the brightness of the CMB (from –100 ppm to + 100 ppm respectively). The spots visible in the image have a typical size of 1°. This characteristic size of the fluctuations corresponds to the dimensions of the sound horizon (i.e. the distance sound waves have travelled in the ionized universe since the big bang) at the recombination. In fact, only perturbations smaller than the sound horizon at that epoch can oscillate like sound waves, thus producing significant anisotropies in the CMB.

The size of the horizon can be computed with good accuracy and compared with the angular dimension observed in the image, thus carrying out a sensitive 'angular-size versus distance' test. From the comparison it is inferred that the curvature of the universe is close to zero. According to the general relativistic cosmological models (see GENERAL THEORY OF RELATIVITY and COSMOLOGICAL MODEL), the curvature of the universe is determined by its average mass–energy density. A density larger than the critical density produces a positive curvature, a density equal to the critical one produces a flat (zero curvature) Euclidean geometry, while a density smaller that the critical one produces a negative curvature. If the curvature

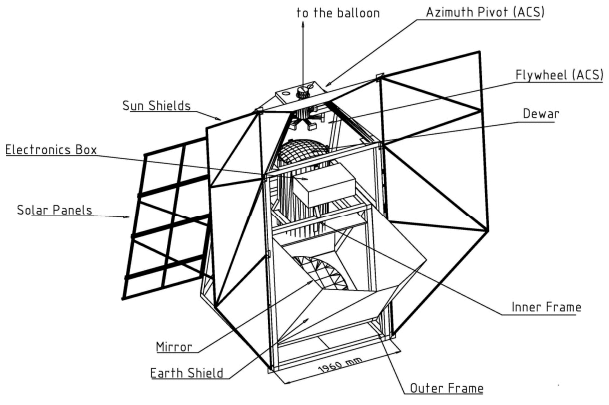

Figure 1. The BOOMERANG payload is a remotely operated microwave telescope. Its mass is about 1.5 tons and it is lifted to 37 km of altitude by a 1 million m^3 helium-filled stratospheric balloon.

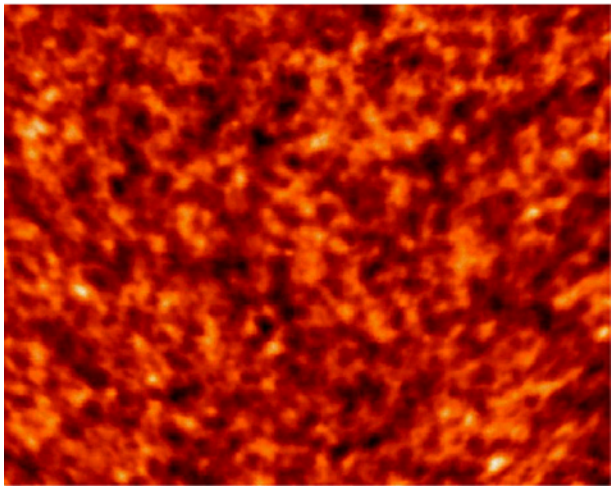

Figure 2. Map of a remote region of the universe obtained by the BOOMERANG experiment at 2 mm of wavelength. The size of this map is about 40° x 50°.

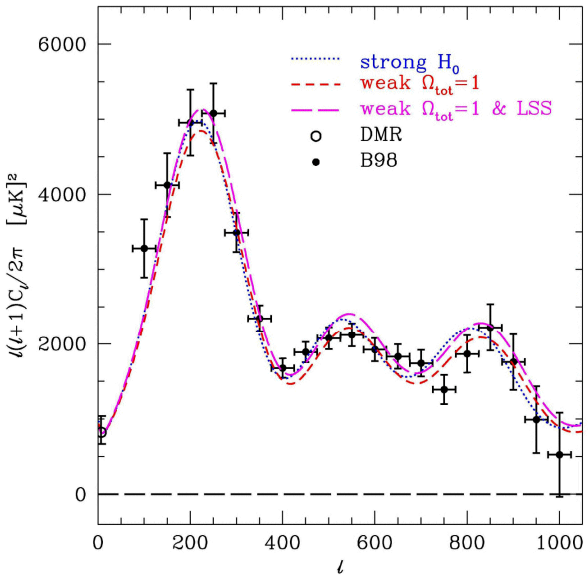

Figure 3. Angular power spectrum of the CMB measured by the BOOMERANG experiment. The quantity plotted is the intensity of the CMB temperature fluctuations for different angular scales, identified by the multipole number. A multipole 200 corresponds to an angular scale of abot 1°. A multipole 1000 corresponds to an angular scale of about 0.2°. The crosses represent the measured data with their statistical errors; the lines represent different adiabatic inflationary models fitting the data.

was positive, the spots would appear larger than observed, while if it was negative the spots would appear smaller than observed. Measuring a curvature close to zero, BOOMERANG has demonstrated that the mass–energy density of the universe is close to the critical density ($\Omega = 0.98 \pm 0.05$). The details of the size distribution of the hot and cold spots in the image (i.e. the angular power spectrum of the CMB; see figure 3) have been compared with accurate theory predictions in the framework of the adiabatic inflationary cosmology with a Hubble parameter h=0.71±0.08. In this way the values of several other cosmological parameters, such as the physical density of baryons ($\Omega_b h^2$), the tilt of the power spectrum of primordial density perturbations (n) and the energy in the form of the cosmological constant (Ω_Λ) have been measured: $\Omega_b h^2 = 0.021 \pm 0.004$; $n=0.94 \pm 0.09$, $\Omega_\Lambda=0.62 \pm 0.15$.

Boscovich, Ruggero Giuseppe (1711–87)

Mathematician, born in Ragusa, Dalmatia, Venetian territory (now Dubrovnik, Croatia), professor at the Collegium Romanum in Rome and Pavia, and director of the Brera Observatory. Using NEWTON's gravitational theories, Boscovich was the first to give a procedure to compute a planet's orbit from three observations of its position, a solution that was elaborated by CARL GAUSS, LEGENDRE and other mathematicians. He studied optics, astronomy, gravitation, meteorology and trigonometry. He wrote in 1753 a crisp and elegant little book on reasons to think that the Moon has no atmosphere, and he led an expedition to California in 1769 to observe the transit of Venus.

Boulliau, Ismael (1605–94)

Mathematician, librarian, priest, born in Loudun, France. In 1645 he published *Astronomia Philolaica* which, on the basis of elliptical orbits for planets and Kepler's laws, suggested that the force which attracted planets to the Sun should vary inversely as the square of the distance (JOHANNES KEPLER had claimed inversely as the first power). This was the most significant advance in the theory of gravitation between Kepler and ISAAC NEWTON. It was acknowledged by Newton in his *Principia*. (*See also* ROBERT HOOKE.)

Bouvard, Alexis (1767–1843)

French astronomer, born a shepherd boy in Chamonix, became assistant to Laplace and eventually director of the Paris Observatory. Attempted to produce an accurate orbit of Uranus, calculating the perturbations of other planets according to corrected tables of planetary positions by JEAN DELAMBRE, published in 1792. Bouvard still could not make all the observations fit. He published his new orbit of Uranus in 1821 but noted: 'I leave to the future the task of discovering whether the difficulty of reconciling [the data] is connected with the ancient observations, or whether it depends on some foreign and unperceived cause which may have been acting upon the planet'. URBAIN LEVERRIER and JOHN ADAMS showed that the latter, Neptune, was the reason.

Bowen, Edward George ['Taffy'] (1911–91)

Radioastronomer, born in Cockett near Swansea, Wales. After war-time research on the development of radar, Bowen went to Australia where he made rain through cloud-seeding, discovered still-disputed correlations between the dates of meteor showers and the lunar phase and rainfall (which he attributed to lunar modulation of meteoritic material) and became a radioastronomer. Inspired by the Jodrell Bank reflector, he organized the construction of the Parkes Radio Telescope to design principles by Barnes Wallis (later Sir Barnes Wallis), the famous airship and aircraft designer, and played the key role in organizing the construction of the Anglo-Australian Telescope.

Bradley, James (1693–1762)

Astronomer, born in Sherborne, Gloucestershire, England. From 1742 third Astronomer Royal. With SAMUEL MOLYNEUX discovered the 'aberration of light' (a very large and unsuspected apparent motion of the stars that was, up to that time, an uncontrolled error in star observations). The explanation for the discovery (the addition of the Earth's orbital velocity to the velocity of the light incoming from the star being measured) provided the first observational proof of the Copernican hypothesis that the Earth moved round the Sun, and showed that the speed of light was a constant of physics. The discovery showed as a by-product that the parallax of stars is very small, i.e. their distances are immense—in the case of Gamma Draconis, the star measured, more than 400 000 times the distance of the Sun. Bradley also discovered that the inclination of the Earth's axis to the ecliptic is not constant ('nutation').

Breccia

A type of rock composed of small, shattered and crushed (and sometimes melted) angular fragments cemented together in a finer-grained material. Breccias are produced by impacts. The shock from the impact of even a meter-sized body on a planetary surface may be sufficient to compact and weld surface material into breccias. Lunar highland rock sampled by the crews of Apollo missions proved to consist of breccias, which are expected to make up the surfaces of all rocky bodies which have not been subsequently modified by volcanic or other geological activity. The fact that many chondritic and achondritic meteorites are breccias shows that they were once part of larger bodies that suffered impacts.

Bright Quasar 3C 273

QUASARS are the most luminous objects we know in the universe. 3C 273 is among the brightest quasars; it also happens to be one of the closest to the Earth. It is therefore bright in the night sky and hence has been the object of intense studies since its discovery in 1963.

Quasars are found in the center of some galaxies (collections of some hundred billion stars; the MILKY WAY is the galaxy in which our solar system is embedded). Quasars are very peculiar celestial objects, they outshine the galaxy that hosts them, although they are barely as large as our solar system (which is extremely small compared with the galaxy). They emit electromagnetic radiation that covers all the bands accessible to astronomical observations on the Earth and in orbit, from radio waves to gamma rays. Their energy radiation can vary in an important manner on time scales that may be as short as hundreds of seconds. The matter close to the most central region of quasars moves at speeds of several thousand kilometers per second. These properties are most likely due to the presence in the center of quasars of a black hole that may be as massive as many tens of millions of suns. This paradigm is the only one that gives some hope of understanding the general properties of these objects.

The discovery

Quasars were discovered in 1963 when it became possible to localize with precision RADIO SOURCES in the sky. 3C 273 played a major role in the discovery of quasars. 3C 273 is a bright radio source, it bears the number 273 in the third Cambridge catalog of radio sources (hence the name). It was the second source that was identified with a very peculiar 'star', a source of light that was not resolved as extended on photographic plates. The 'star', or better the source of optical light that was coincident with the radio source 3C 273, was soon seen to have peculiar emission lines. These are the signature of the presence of atoms that are excited and emit light at well defined wavelengths. Stars normally don't have emission lines, and more surprisingly it was at first impossible to recognize the type of atoms that were responsible for the emission lines in 3C 273, as the wavelengths at which the lines were observed were not among those emitted by known atoms. These very peculiar properties of the light source led to the name quasi stellar radio source that then became QSO for quasi stellar object or quasar for quasi star.

The mystery of the emission lines was solved when it was noted that one could indeed recognize the wavelength of the emission lines if one admitted that the lines are observed not at the wavelength λ_0 typical of laboratory measurements of the atoms but at longer wavelengths $\lambda = \lambda_0(1 + z)$, where z is known as the redshift, equal to 0.158 for 3C 273. Many galaxies showing the same effect were already known in 1963, but with redshifts much less than that of 3C 273. In the universe this effect is a sign that the objects are moving apart from one another (expansion) and thus are at very large distances. At a redshift of 0.158 3C 273 is thus found to be some 3 billion light years away. In 1963 3C 273 was the most distant object known (see also HIGH-REDSHIFT QUASARS).

Being so far away and still easy to find on photographic plates, 3C 273 is an object of 13th magnitude; 3C 273 is clearly a very luminous object indeed. Its light output corresponds to 10^{14} times that of the Sun.

Most quasars do not radiate substantially in the radio part of the electromagnetic spectrum, and are called radio quiet quasars. A small fraction, of which 3C 273 is a member, do, however. These quasars are called radio bright quasars. They can be discovered as described above using radio data. Radio quiet objects are found by looking for redshifted emission lines in the light of 'stars'.

It was also soon discovered that 3C 273 varies in intensity on time scales much less than 1 year. Since light sources cannot vary on times scales much less than the time the light needs to cross the source (this is due to a causality argument: in order to significantly change the brightness of an object a signal must reach all the parts of the object to convey the instruction), it was also very quickly clear that 3C 273 must be much smaller than 1 light year, a distance already much less than that separating us from the closest star in our Galaxy.

The very unusual properties of 3C 273 spurred a large set of observations using not only optical and radio telescopes but also other instruments, both on the ground and on Earth orbiting satellites. It became clear that this (and other) quasar was the source not only of visual light and radio waves, but also of infrared radiation, ultraviolet light, x-rays and gamma rays.

Deep radio, optical and x-ray images in subsequent years showed that the object is not really 'star-like' but that a cigar shaped extension is associated with the main source (see figure 1 of QUASISTELLAR OBJECTS: OVERVIEW). This 'jet' extends from very small distances to some 20″ from the 'core'. It is most prominent in the radio images. Very surprisingly, the features making up the jet (often called blobs, thus expressing our lack of understanding of these features) were seen to travel away from the core of the object at speeds seemingly larger than the speed of light (superluminal motion). This superluminal motion is in fact due to an aberration that takes place when objects are moving in a direction close to the line of sight at velocities close to (but not larger than) the speed of light. This showed that in addition to the already very unusual observed properties of quasars one had to add the presence of radio wave emitting matter moving at very high speeds along a well defined direction, close to the line of sight.

The source of energy

The only way known to us through which large quantities of energy can be released by matter in a very small volume, clearly necessary properties to understand the nature of quasars, is to consider that the matter falls into a very deep gravitational potential well created by a very massive and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

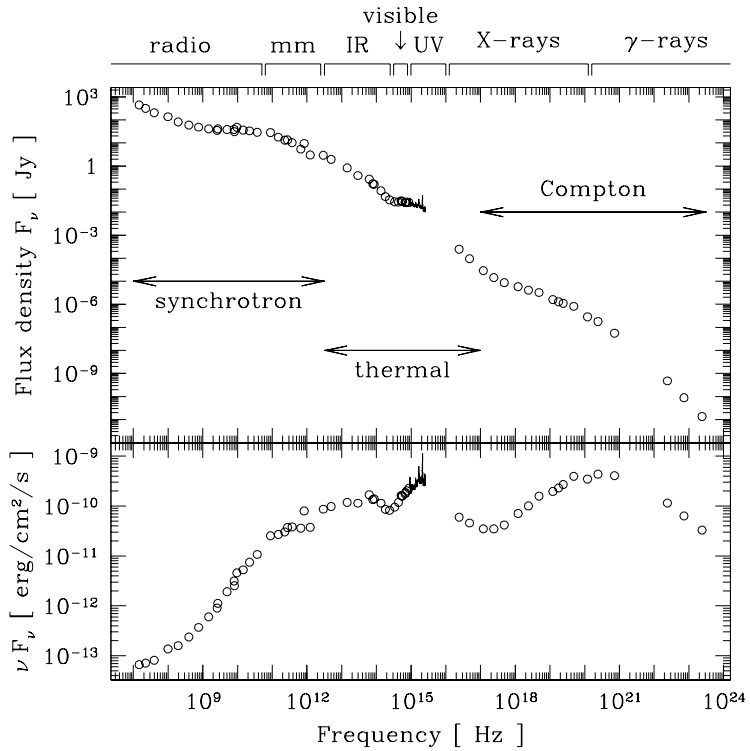

Figure 1. The observed energy per unit area per unit time and per unit frequency (flux density) from quasar 3C 273 is given in the top panel. The emission mechanisms responsible for the emission are mentioned. The bottom panel expresses the same observations per log frequency interval. This shows that we observe roughly the same energy in all regions of the electromagnetic spectrum over 10 decades of frequency.

compact object. It is thus now accepted that quasars host very massive BLACK HOLES into which matter is falling at a high rate. One can estimate the mass of the black hole in the center of 3C 273 by remembering that light exerts a pressure on matter. The gravitational pull must be larger than this pressure for the matter to fall and its gravitational energy to be released. For 3C 273, the mass of the central black hole that is implied by this reasoning is about one billion solar masses.

The mass of the black hole provides a measure of its size; in the case of 3C 373 this size is of the order of 10^{12} m. The corresponding light crossing time is 10 000 s or a few hours. This is well compatible with the fact that quasars (and in particular 3C 273) vary very rapidly.

It is also possible to estimate how much matter must fall into the black hole to explain the observed luminosity by noting that the energy released by the fall is a fraction of the in-falling mass multiplied by the square of the velocity of light. This fraction is of the order of 10%. Again in the case of 3C 273, one finds that the rate of mass in-fall is about the mass of the Sun per year.

Going beyond these simple estimates to understand the true nature of quasars has proved a very difficult endeavor, that is still nowhere close to being finished. This is due to the very unusual properties of the objects compared with the better known celestial bodies and to the very complex geometry of the sources. The latter property prevents one approximating quasars by spherical objects, the properties of which are identical when viewed from different directions. In quasars it appears that the observed properties strongly depend on the direction from which they are viewed.

The radiation of quasars

The energy radiated by quasars is gained from the gravitational binding energy of the matter that falls into the black hole. This energy is radiated by elecrons through several emission mechanisms. Electrons moving along bent paths radiate part of their energy as electromagnetic radiation. In quasars there are many ways through which the paths of electrons are bent; there are correspondingly many emission mechanisms. Magnetic fields are one way of bending electron paths. The radiation emitted by these electrons is called SYNCHROTRON RADIATION. With the parameters typical of quasars this energy appears as radio and millimetre waves. Hot electrons also move along complex paths in the thermal medium. These therefore also radiate what is called thermal radiation. In quasars thermal radiation is observed from heated dust in the infrared part of the electromagnetic spectrum and, most probably, by material heated in the process of the fall towards the black hole. This radiation appears in the

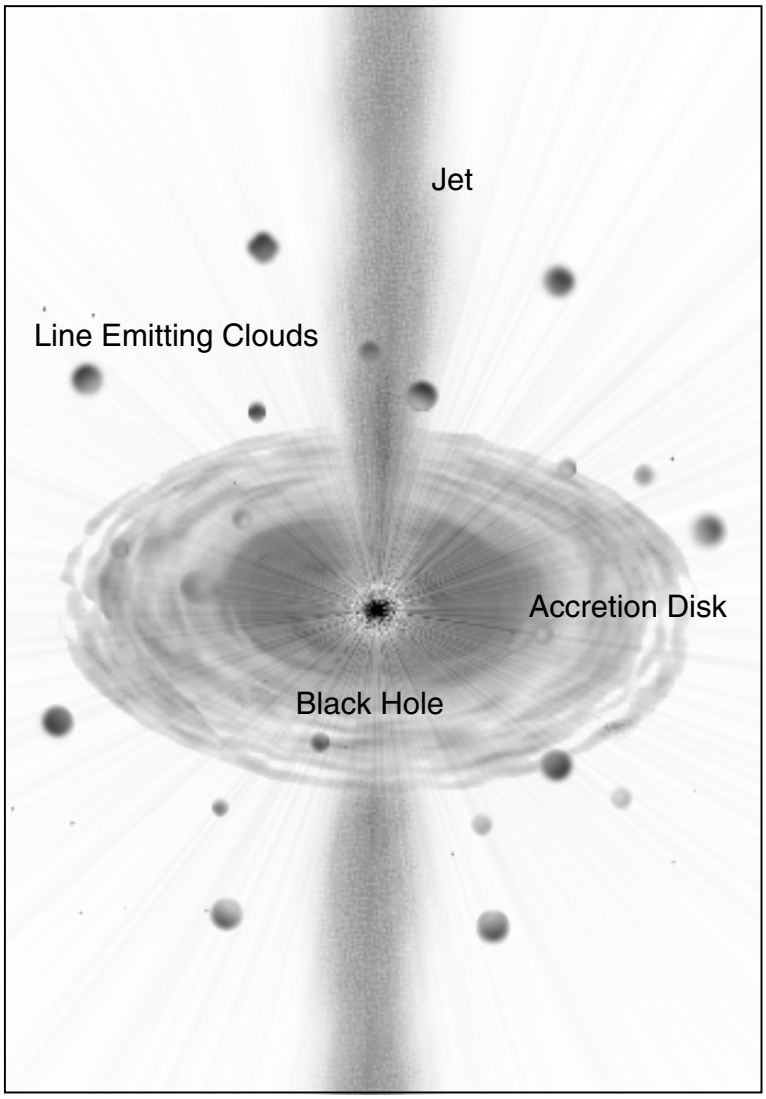

Figure 2. A popular view of the different elements making a quasar like 3C 273. The matter falls into the black hole on spiral paths in the accretion disk. The jet originates at the center of the disk. The line emitting clouds orbit the black hole.

visible and ultraviolet parts of the spectrum. A further way of bending the paths of electrons is through interaction with ambient light. These interactions are called Compton processes. Depending on the energy of the electrons the resulting emission appears in the x-ray or in the gamma ray parts of the spectrum.

We give in figure 1 the energy flux received at the Earth from the quasar 3C 273 and show which parts of this flux are caused by the mechanisms sketched above. We also give in the same figure the flux per logarithmic frequency interval (νF_ν). This representation gives the quantity of energy we receive in each region of the electromagnetic spectrum, i.e. as radio, millimeter, infrared, visible, ultraviolet, x-ray or gamma rays. It is striking to note that we observe roughly the same quantity of energy in all these regions of the spectrum. This is described here for 3C 273; it is true in the same way for other radio bright quasars and with the exception of the radio emission for the radio quiet quasars. This is undoubtedly due to the interactions that exist between the different building blocks of the quasar.

Understanding these interactions is a question of intense research. The approach that is being mostly used is based on repeated observations of the quasar in as many parts as possible of the electromagnetic spectrum. One then uses the variations observed in different parts of the spectrum to see which variations lead others in time. One thus expects to slowly understand what are the more fundamental phenomena and what are the components that are secondary. One also hopes to understand the relative organization of the regions emitting through the components described above. This will hopefully lead to

Dirac House, Temple Back, Bristol, BS1 6BE, UK

a description of the geometry of the quasar.

One possible geometry is based on the presence of an ACCRETION DISK around the black hole. In this disk the material is slowed down by viscous forces and thus slowly falls towards the black hole, releasing its gravitational energy. These disks are called accretion disks; they are known to exist around much less massive compact objects within our galaxy. Their presence is rather naturally expected also around the much more massive black holes in the center of external galaxies. The jet is then ejected perpendicular to the disk, at its center. The emission lines are emitted by small clouds that orbit the system. This geometry is illustrated in figure 2. It should be noted that this is a possible way of understanding the organization of matter in quasars and is not yet firmly established.

The future

Quasar 3C 273 was the first in which the very peculiar nature of these objects was recognized. It has been the object of intense studies in the 30 years since its discovery. Many of the observations have led to new insights and to more surprises. 3C 273 is certainly the best observed quasar and thus the best known. All the phenomena that are associated with quasars are seen in 3C 273, whether this makes it the archetype of a quasar or an exceptional object remains to be seen. What is certain is that understanding the physics of 3C 273 is still a challenge.

Brisbane, Thomas Makdougall (1773–1860)

Soldier and astronomer, born in Largs, North Ayrshire, Scotland. After a distinguished army career, he became Governor of New South Wales (1821), initiating largely unsuccessful experiments to introduce tobacco, coffee, cotton and flax to Australia. He had built only the second observatory in Scotland at the family home of Brisbane House in 1808, and built an observatory at Parramatta in New South Wales, making the first observations of 7385 stars in the southern hemisphere since NICHOLAS LACAILLE's in 1752. On return to Scotland, built an observatory at Makerstoun and became president of the Edinburgh Astronomical Institution. He is possibly the only astronomer to have a major city named after him (Brisbane, the capital of Queensland).

British Astronomical Association

The British Astronomical Association was founded in 1890 and has 3000 members. It is open to anyone interested in astronomy and it aims to bring together like-minded amateur astronomers, to collect their observations and organize their observational efforts under the guidance of experienced Section Directors. Papers and current astronomical observations/information are circulated by way of a journal, web page, handbook, circulars, memoirs, section publications and library. It hopes to encourage a popular interest in astronomy. Meetings are held in London and major cities throughout Great Britain. The registered office of the Association is at Burlington House, Piccadilly, London W1V 9AG.

British Astronomy

There has been a unified culture of astronomy in Britain, extending over the whole of the British Isles, ever since prehistoric times.

Prehistoric astronomy

The earliest surviving evidence of an interest in astronomy by the inhabitants of the British Isles lies in the alignments of megalithic monuments. Stonehenge in Wessex (2700 BC–) has alignments over the Heel Stone towards midsummer sunrise and could be, in principle, used to predict eclipses. The Temple Wood circle in Argyllshire (2nd millennium BC) appears to be a lunar observatory. The Newgrange barrow in the Boyne valley contains a unique 'roof-box' which admits the rays of the rising Sun at the midwinter solstice into the grave passage. Thus, in prehistoric times, it appears that there was a priestly clan in England, Scotland and Ireland, culturally connected in technology and intellectual knowledge, which included astronomical observation and possibly even prediction.

Archaeological evidence shows that the Roman occupation of Britain (55 BC–c AD 400) brought a knowledge of practical astronomy, including timekeeping and calendrical calculations. This knowledge was maintained, pretty much with its original theoretical bases but elaborated into sophisticated formulae, for example the calculation of Easter by Bede (672–735), a monk in Jarrow.

Medieval astronomy

Islamic astronomy came to Britain in the medieval period. JOHN OF HOLYWOOD, known as Sacrobosco (1195–1256), learnt astronomy in Britain and moved to Paris where he provided his students with a textbook on astronomy, *The Sphere*. A watered-down version of John of Seville's translation of *The Elements* by Al-Farghani, it was the long-term, best-selling, standard textbook in astronomy until the 17th century (it was published in 200 editions in the age of printing), even if it was barely adequate. Educated people, farmers and sailors, had knowledge of the practicalities of astronomical observations. The poet Geoffrey Chaucer (c 1343–1400) was author of the *Canterbury Tales*, which shows his familiarity with astrological matters, and wrote *A Treatise on the Astrolabe*, the oldest known 'technical manual' in the English language.

Renaissance astronomy

In the 16th century, Britain was, during the reign of Queen Elizabeth I, expanding its trade links overseas, taking the first steps to create an Empire. Astronomy concentrated on the practical matter of navigation, including timekeeping. It seemed less important what model of the solar system was correct than what model gave adequate predictions, so it is no surprise that William Shakespeare showed such a little interest in cosmology, although his knowledge of astronomical phenomena was detailed. His plays show no knowledge of Copernicus. They do show a (somewhat skeptical) knowledge of astrology. The astrologer JOHN DEE (1527–1608) cast horoscopes for Elizabeth, receiving the title Royal Astrologer. He claimed to have put a hex on the Spanish Armada and to have caused the bad weather that wrecked the fleet.

Up to the 17th century the teachers of astronomy in Britain were, in the main, clerics with an interest in proclaiming the glory of God and teaching the 'quadrivium' (the four classical subjects of arithmetic, harmony, geometry and astronomy, knowledge of which made a man educated in science). Copernicus' and Kepler's knowledge of the motions of the planets and Galileo's theory of dynamics were taken up by amateurs, like the group that formed around WILLIAM CRABTREE (1610–1644), a Lancashire instrument maker, and JEREMIAH HORROCKS (1619–1641), a schoolmaster. With his own theory of celestial dynamics, related to Kepler's, Horrocks predicted a transit of Venus, which he and Crabtree observed.

Astronomy in Britain became a cultural pursuit as well as a practical one and was a talking point in educated society. John Donne's poetry covers issues such as the appearance of the supernova of 1604 and the new astronomy of Galileo, which put all in doubt, canceling out the old Ptolemaic certainties. Astronomy in the universities (which meant Oxford and Cambridge) turned from the teaching of Aristotelian and Ptolemaic philosophy and astronomy to the empirical observation of new phenomena. Astronomers formulated scientific laws by induction, often expressed them geometrically and increasingly expressed mathematically.

In the 18th century the Government began to take a structural interest in astronomy. King Charles II was persuaded to found the ROYAL OBSERVATORY, GREENWICH in 1675, in order to provide astronomical predictions for the purposes of navigation, for the benefit of the Royal Navy. The predictions were based by JOHN FLAMSTEED (1646–1719), the Royal Observatory's first director, on careful and precise observations, from which increasingly accurate investigations could be made of astronomical phenomena. At the same time, from the universities, Sir Isaac NEWTON (1643–1727) formulated mathematical theories of motion and gravitation, presented in an equivalent of calculus (but expressed in traditional geometric terms). EDMOND HALLEY (1656–1742) used Newton's theory of gravity to predict the return of the comet that bears his name.

Newton and Flamsteed clashed over the running of the Royal Observatory. Flamsteed wanted the observations to be the best possible, sought grants to make the best equipment and took time to develop the observing techniques. Newton wanted observations too, but quickly in order to test his gravitational theory of the planets and the Moon. They quarreled. This fight between the institutes and the academics recurred in 20th century Britain.

Flamsteed as director of the Royal Observatory had taken the title Astronomer Royal as a sign of the state

position of astronomy as practiced in Greenwich but the British royal court also continued its more personal interests in astronomy, maintaining court astronomers. Sir William Herschel (1738–1822) and his sister Caroline Herschel (1750–1848), at first supporting themselves through musical performances and teaching, constructed telescopes with which they made significant discoveries—comets, nebulae, double stars, even a new planet—and both were rewarded with royal pensions (see HERSCHEL FAMILY). William was given a stipend and the title of Royal Astronomer, getting King George's telescope ready on fine nights to show discoveries to the royal court. The Queen and her ladies took a personal interest in Caroline's comet, the first discovered by a woman, although the male courtiers belittled it as a small one.

The 19th century

Three groups of astronomers had established themselves in the 19th century: amateurs, Government astronomers and university astronomers. The amateurs included the independently wealthy, for example Lord Rosse (1800–1867) and Sir John Herschel (1792–1871). They included businessmen, for example William Lassell (1799–1880), a Liverpool brewer, and James Nasmyth (1808–1890), a mechanical engineer. Both men built telescopes, and Lassell's, erected under the clear skies of Malta, foreshadowed the overseas observatories of modern times. The amateurs also included pensioners such as retired servicemen (Admiral W H Smyth (1788–1865)). The amateurs concentrated on visual observations of planets, nebulae and double stars but also used talent, time and their own resources to construct large, ingenious or novel instrumentation (such as Sir William Huggins' application of spectroscopy and Common's application of photography to astronomy). Rosse built in Ireland (then part of Great Britain) the then-largest telescope in the world, the 6 ft (1.8 m) aperture 'Leviathan of Parsonstown'.

The university astronomers, particularly at Oxford and Cambridge, but later in London, Durham, Manchester, etc, concentrated on the high intellectual content areas of astronomy, typically theoretical mathematical astronomy (at first celestial mechanics, later astrophysics). The Government astronomers were principally at Greenwich (for example Sir George Airy (1801–1892)) and later also at the ROYAL OBSERVATORY, EDINBURGH. Their work could be characterized as systematic observations by teams of astronomers and 'calculators' in programs principally of positional astronomy. They carried on a tradition started in the 18th century by Halley and Cook of overseas travel to observe astronomical phenomena not visible from Britain, such as hidden constellations, transits and eclipses, and founded the Royal Observatory at the Cape in 1825. CHARLES PIAZZI SMYTH of Edinburgh site tested the mountain of El Teide on Tenerife in the Canary Islands, setting the scene for the establishment of the La Palma observatory.

In 1820 the ROYAL ASTRONOMICAL SOCIETY was founded. Some members met at a gentlemen's dining club to discuss the latest developments. The wider society of astronomers met monthly in open session with a formal program of presentations, which were announced and summarized in the Society's *Monthly Notices*. This journal continues as the principal means of publication of professional astronomical research in Britain (with a substantial content from overseas), in modern times among the trio of the world's most important astronomical journals (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS). It retains the historical name, although it is neither monthly nor collections of notices. Reflecting its 19th century origins, the Royal Astronomical Society remains a society of both professional and amateur astronomers, numbering about 3000, but there are additional exclusively amateur astronomy societies such as the BRITISH ASTRONOMICAL ASSOCIATION.

Modern astronomy in Britain

In the 20th century astrophysics became more important in Britain than positional astronomy, and the thrust of the universities in astrophysics began to challenge astrometry at the royal observatories. Theoretical astronomy, especially cosmology, became very strong—this is the period of Sir Arthur Stanley Eddington (1882–1944), E A Milne (1896–1950) and Sir James Jeans (1877–1946). This area of strength continues, for example in gravitational physics around Steven Hawking. In mid-century a generation of young radar scientists (for example Sir Bernard Lovell (1913–), Sir Martin Ryle (1918–1984, Nobel Prize 1974)) returned to the universities (Manchester and Cambridge) from which, as young men, they had been recruited to work in the Second World War, and established radio astronomy. The radio interferometers at Cambridge made all-sky surveys, establishing the evolutionary big bang theory of the universe, demolishing the steady-state theory produced by Sir Fred Hoyle and his associates and discovering pulsars (Anthony Hewish, Nobel Prize 1974). Jodrell Bank's Lovell Telescope was for a time the largest fully steerable dish for radio astronomy. JODRELL BANK OBSERVATORY is now the center of the MERLIN interferometer spread across England. Meanwhile, space astronomy groups established themselves in the universities of London, Leicester and Birmingham, developing x-ray astronomy, solar astronomy and magnetospheric physics. The number of astronomical knighthoods signifies continuing public, establishment and royal support for astronomy.

The Royal Observatory moved out of London to less smoky, less light-polluted skies over Herstmonceux in the south of England, keeping its link with Greenwich in its new name. As celestial navigation became less important for ships, the Royal Greenwich Observatory shifted its emphasis towards scientific research. In 1965 it was transferred from the control of the Royal Navy to one of the new British Government bodies set up to fund scientific research, the Science Research Council (later the Science and Engineering Research Council, still later the PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL, which is the currently operating UK funding agency for astronomy). The Government-funded research councils

were given university-oriented mission statements and controlled by governing bodies with members from the universities, whose number, power and influence were growing with the increase of tertiary education in Britain.

The optical astronomers proposed a large 2.5 m aperture telescope. Because of its established position of power, it was the Royal Greenwich Observatory, under Sir Richard van der Riet Woolley, which built the Isaac Newton Telescope (1967). It did not satisfy the universities' needs. During study overseas, university astronomers had used telescopes in good climates such as California and did not like sitting under cloudy skies at night in Sussex. Also they did not easily relate to the civil service style of operation of the telescope.

A southern hemisphere facility had become important to the space astronomers with their all-sky capability. They pressed for the establishment of the ANGLO-AUSTRALIAN OBSERVATORY in Coonabarabran (1974). The EUROPEAN SPACE AGENCY was formed in 1975 and its Science Program to launch astronomical telescopes and to explore geospace and the planets has become Britain's main space astronomy program. The UK takes a high profile and active interest in ESA and its Science Program.

Infrared astronomers sought out a high site, Mauna Kea, Hawaii, for the UNITED KINGDOM INFRARED TELESCOPE (1979), operated by the Royal Observatory, Edinburgh. Later, the JAMES CLERK MAXWELL TELESCOPE for millimeter astronomy was established there. The radio astronomers pressed for an optical 'northern hemisphere observatory' to follow up their radio observations made from Britain. It was created by the move in 1984 of the Isaac Newton Telescope to La Palma in the Canary Islands. The main telescope at the observatory was completed in 1986, the 4.2 m William Herschel Telescope.

The Royal Greenwich Observatory continued to operate the telescopes in La Palma but, having lost its main telescope to an overseas site, it was moved for a second time in 1991, to the university environment of Cambridge. There was competition for resources between the two Royal Observatories (Greenwich and Edinburgh) and the universities. This led in 1998 to the closure of the Royal Observatories in Cambridge and Edinburgh and the establishment in Edinburgh of a combined UK Astronomy Technology Center to make astronomical instruments at the site still called the Royal Observatory, Edinburgh. In 1999 the first of the two 8 m Gemini Telescopes was opened on Mauna Kea, with the second soon to be established in Chile.

All Britain's current large telescopes (save MERLIN and UKIRT) are multinational, with Britain partnering Australia, Canada, the Netherlands, Spain, the USA and other countries. The UK is not however currently a member of ESO, having declined to join on grounds of expense at its foundation, and presently rueful about missing out on participation in the VLT.

In Britain today there are about 6000 amateur astronomers (judging by membership of the amateur societies, allowing for overlaps). By contrast with many continental European countries, professional astronomy has become dispersed into the universities, no longer concentrated into special institutes. There are 50 universities that teach astronomy at an undergraduate level (see EDUCATION). About half of these have significant astronomy research groups. British astronomers produce about 10% of the world's output of astronomy (about a quarter that of the USA, to whom the UK lies in second place, and about the same as France and Germany). There are some 300 permanent university astronomers, 400 post-doctoral researchers with fixed-term positions and some 450 PhD students, many of whom are independently financed. About 25% of the PhD students remain in astronomy after a decade—most transfer their skills to industry. The number of university teachers shows a steady increase, financed by the universities in response to an increasing student demand. Public interest in astronomy as a high-profile, flagship science remains strong and increasing and there is virtually daily coverage of astronomy in the UK's newspapers and broadcast MEDIA. However, the Government funding for astronomy is flat (at £95 m p.a. in 1999). Indeed there has been small but steady reduction in Government-provided purchasing power for astronomy for 15 yr, a dramatic fall in the number of astronomers employed by the Government institutes and a recent decrease in the number of doctoral and post-doctoral researchers. In spite of this, perhaps because of the competitive nature of the university environment, British astronomers are international, dynamic and flexible and, at the present time, in spite of chronic financial stress, remain successful in continuing Britain's 4000 yr old attempt to understand the universe.

Brouwer, Dirk (1902–66)

Celestial mechanician, born in and educated in The Netherlands, director of the Yale University Observatory. He determined the mass of Titan from its influence on other Saturnian moons, and developed methods for finding orbits of comets, asteroids and planets, redetermining the astronomical constants. He was one of the first to use electronic computers for astronomical computations, computing the orbits of the first artificial satellites, obtaining increased knowledge of the figure of the Earth. He was editor of the *Astronomical Journal*.

Brown, Ernest William (1866–1938)

Celestial mechanician, born in England, taught mathematics at Haverford College in Pennsylvania and at Yale University. Devoted his life to calculations of the Moon's motion. His theory, which was a set of equations with an astounding 1500 terms, took account of 'the gravitational action of every particle of matter that can have a sensible effect on the Moon's motion'. He computed the constants of the terms by analysing 150 years of Greenwich observations.

Brown, Robert Hanbury (1916–)

Physicist, astronomer. Educated in London, after wartime service became radioastronomer at Jodrell Bank, where he discovered that M31 is a radio source; professor at University of Sydney. Despite being assured, by colleagues who understood less quantum mechanics than he did, that it was impossible, he invented the Intensity Interferometer, which created wave-like interference in optical sensors after the incoming light had been detected. Used the interferometer, constructed at Narrabri in Australia, to determine the angular diameters of the brighter stars.

Bruno, Giordano (1548–1600)

Philosopher, born in Nola, near Naples, Italy as Filippo, took the name Giordano upon becoming a Dominican. Was taught Aristotelian philosophy in the Dominican monastery in Naples, but became attracted to Plato and Hermes Trismegistus and came to the unwelcome attention of the Inquisition, a situation possibly exacerbated by his intemperate, disputative style. Self-exiled to France and England. Published *Cena de le Ceneri* (*The Ash Wednesday Supper*) in which he defended the heliocentric theory of Copernicus, and *De l'Infinito, Universo e Mondi* (*On Infinity, the Universe and its Worlds*) in which he argued that the universe was infinite, that it contained an infinite number of worlds, and that these are all inhabited by intelligent beings. Unwisely returning to Italy (Venice and Rome) he was arrested by the Inquisition, imprisoned and tried. In the end, he refused to recant, was declared a heretic and burned at the stake. The precise grounds for his execution are not known because his file has not been seen, but it is often maintained that Bruno was executed because of his Copernicanism and his belief in the infinity of inhabited worlds. Bruno was the first Renaissance scientist to adopt the atomist philosophy of Democritus and Lucretius.

Bubble Nebula (NGC 7635)

A faint diffuse nebula in the constellation Cassiopeia, position RA $23^{h}\ 20.7^{m}$, dec. $+\ 61^{\circ}\ 12'$, appearing as a $3'$ diameter bubble surrounding a seventh-magnitude star. The bubble is a spherical shell of gas apparently shed by the central star, although it does not appear to have the characteristics of either a planetary nebula or a supernova remnant.

Buffon, Georges Louis Leclerc Comte de (1707–88)

French naturalist. Discovered the binomial theorem and worked on probability theory. In astronomy he suggested that the Earth might have been created by the collision of a comet with the Sun. Based on the cooling rate of iron, he calculated in *Théorie de la Terre* that the age of the Earth was 75 000 years. This estimate, so much larger than the official 6000 years, was condemned by the Catholic Church in France, which burned Buffon's books.

Bulgarian Academy of Sciences, Institute of Astronomy

The Institute of Astronomy of the Bulgarian Academy of Sciences (IABG, BAS) is located in Sofia. Its activities include fundamental research in astronomy and astrophysics and teaching. The Institute was established in 1995 as a successor of the Section of Astronomy (SA) and National Astronomical Observatory 'Rozhen' (NAO). Professor Nikola Bonev was the founder (in 1958) and the first director of SA. In 1995, the first director of the newly established IABG was Professor Vladimir Shkodrov. Its total staff is 90 including 42 scientists and 34 PhD holders. Two modern observatories for optical studies belong to the IABG: the National Astronomical Observatory 'Rozhen' (long: −1 h 38 m 52 s; lat: +41 deg 43′; altitude: 1750 m) and the Observatory in Belogradchik (long: −1 h 30 m 42 s; lat: +43 deg 38′; altitude: 630).

The main telescope of NAO is a 2 m Ritchey–Chrétien Coudé made by Carl Zeiss Jena and equipped with a 1024 × 1024 Photometrics CCD camera. The Coudé spectrograph provides dispersions of 4 Å, 9 Å and 18 Å. At present, it is the biggest optical telescope in SE Europe. The other telescopes of the NAO are: 60 cm Cassegrain with a UBV photometer, 50/70 cm Schmidt (5 × 5 deg) and an 18 cm photoheliograph refractor for solar studies. The BO is equipped with a 60 cm Cassegrain photometric telescope. Research departments of the IABG include: Sun, solar system, non-stationary stars, stellar atmospheres and envelopes, chemically peculiar stars, stellar clusters and galaxies. The budget for 1999 was 400 000 DM (from the state) and 7000 DM (from the National Science Foundation). Several international organizations participate: International Astronomical Union, European Astronomical Union, The New York Academy of Sciences, etc. International agreements cover joint research projects with the astronomical institutes of Germany, France, Poland, Russia, Italy, etc.

Burbidge, Eleanor Margaret Peachey (1919–)

Astrophysicist, born in Devonport, Devon, England, worked in London, Yerkes Observatory, Cambridge, the California Institute of Technology, the Royal Greenwich Observatory and University of California at San Diego. Married and collaborated with Geoffrey Burbidge, a theoretical physicist. It is said that in the days when women were not permitted to observe in their own right with the 200 in telescope, it was Geoffrey who signed Margaret's applications to use it, and read astronomical journals and dozed in its control room while she worked through the night. She collaborated with her husband, FRED HOYLE, and WILLIAM FOWLER in a paper, universally known from its authors' initials as B^2FH, on the synthesis of the chemical elements beyond helium in stars. She used the spectra of galaxies to determine their rotations, masses and chemical composition, and elucidate the properties of their peculiarities and central cores (quasars).

Byurakan Astrophysical Observatory

Located 40 km north of Yerevan in the former Soviet Republic of Armenia. Founded in 1946 through the initiative of astronomer Victor Ambartsumian, it is now the home of the Astrophysical Observatory of the Armenian Academy of Sciences. By late 1999, the only telescope still functioning was the main 2.6 m reflecting telescope.

Caelum

(the Chisel; abbrev. Cae, gen. Caeli; area 125 sq. deg.) A southern constellation that lies between Eridanus and Columba, and culminates at midnight in late November. It was named Caela Sculptoris (the Sculptor's Chisels) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2. The shortened form was adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest star in Caelum is of magnitude 4.4. Interesting objects include γ^1 Caeli, a binary with orange (K2) and white components, magnitudes 4.7 and 8.5, separation 3″, and R Caeli, a Mira-type variable star (range 6.7–13.7, period about 391 days). There are no bright star clusters, nebulae or galaxies in Caelum.

Cagliari Astronomical Observatory

The Cagliari Astronomical Observatory was established in 1899 as the International Latitude Astronomical Station of Carloforte, a small town on the Sardinian island of San Pietro. For about 80 years it has been one of five international stations devoted to the study of Earth's rotation and polar motion.

Observations with its zenithal telescope were only interrupted during the Second World War. Since 1978, its headquarters have been at Punta Sa Menta, a site 15 km (9 miles) from Cagliari, which has the same latitude as the Carloforte station.

Astrophysical research is mainly devoted to the study of the Diffuse Interstellar Bands in the interstellar medium, using the Coude Echelle Spectrograph at the EUROPEAN SOUTHERN OBSERVATORY in Chile. It is also the site of a satellite laser ranging station.

Calar Alto Observatory

The Calar Alto Observatory, or 'Centro Astronomico Hispano-Aleman', is located at an altitude of 2168 m in the 'Sierra de los Filabres', in southern Spain. Its construction on Calar Alto mountain began in 1973. It is operated jointly by the MAX-PLANCK-INSTITUT FÜR ASTRONOMIE in Heidelberg (MPIA), Germany, and the 'Comision Nacional de Astronomia'. The MPIA provides four telescopes of diameters 3.5 m, 2.2 m, 1.23 m and a 0.8 m Schmidt telescope. The 'Observatorio Astronomico Nacional' (OAN) independently runs a 1.5 m telescope.

Telescope time is awarded semi-annually through peer-reviewed proposals. Typical time allocation for the MPIA telescopes is 40% for MPIA, 50% for other German institutes and 10% for the Spanish community. Calar Alto facilities may also be used by guest observers from any other country.

Instrumentation is state of the art and provides competitive and complementary facilities. It includes an adaptive optics system (ALFA) which employs a sodium artificial laser guide star system, various near-infrared cameras (OMEGA Prime, OMEGA Cass, Magic) with spectroscopic and polarimetric capabilities, a fiber-fed echelle spectrograph (FOCES) and focal reducers providing multi-object spectroscopy (CAFOS, MOSCA), among others.

Calendar

A calendar is a system of organizing units of time for the purpose of reckoning time over extended periods. The DAY is the smallest calendrical unit of time; the measurement of fractions of a day is timekeeping. Some calendars replicate astronomical cycles according to fixed rules, others are regulated by astronomical observations. Commonly, calendars take the form of reckoning time with reference to the beginning, length and divisions of the YEAR. They are presented as a tabular arrangement of the days of each MONTH and week in a year.

The periods of the motions of the Sun and Moon and the daily rotations of the Earth have been the natural bases for development of calendars. However, some civilizations have based calendars on other solar system bodies, such as the Mayan use of Venus. Unfortunately, none of the natural resulting periods (year, lunation or day) are exact multiples of the other. Thus, calendars based on lunar months require adjustments to remain close to the year based on the apparent motion of the Sun. The exact period of the Earth's motion around the Sun is not an integral number of days, so it requires adjustments to keep the seasons, or more significantly the religious holidays, at the same times in the calendar. The seasons and some religious holidays are derived from natural body motions. Some are defined in terms of the vernal EQUINOX, which strictly follows the motion of the Earth. There is an ecclesiastical equinox defined to permit the determination of Easter without variations due to the true motion.

The tropical year is defined as the mean interval between vernal equinoxes. The current mean value of the tropical year is 365.242 190 days. The value decreases due to tidal braking by six millionths of a day per century. The true interval from a particular vernal equinox to the next may vary from this mean by several minutes. The exact length of the tropical year is dependent on the general planetary theory or numerical integration used to determine the orbital elements.

The current calendar used internationally is the Gregorian calendar. This was introduced by Pope Gregory in 1582 in some countries and as late as 1927 for others. The Gregorian calendar has 365 days per year except for leap years of 366 days. Leap years are years evenly divisible by 4, except for years that are exactly divisible by 100; these centural years are leap years only if they are exactly divisible by 400. Thus, 1800, 1900, 2100 and 2200 are not leap years, but 2000 is a leap year.

The Gregorian calendar year is 365.2425 days long compared with the current tropical year of 365.242 190 days, a difference of 0.000 310 days, or 1 day per 3000 years. The INTERNATIONAL ASTRONOMICAL UNION (IAU) has adopted the Julian year of 365.25 days as a time unit for many computations such as precession and orbital elements, to avoid the variability and uncertainty of the value of the tropical year. There have been unconfirmed statements of modifications of the Gregorian calendar by some countries to correct for this remaining discrepancy. However, there are no known corrections for long-term discrepancies, and improved ephemerides may change the magnitude of the discrepancy.

Also there are frequent radical proposals for simplifying, standardizing or improving the Gregorian calendar. The current total international use of the Gregorian calendar will require that any change must offer a worldwide benefit that justifies the change.

In many cases calendars have been based on the lunar cycle. The synodic month, the mean interval between conjunctions of the Moon and the Sun, corresponds to the cycle of lunar phases. The mean value of the synodic month is 29.530 589 days and increases due to tidal effects by two millionths of a day per century. Any lunar phase cycle can deviate from the mean by up to 7 h.

Some lunar calendars (e.g. Islamic) begin a new month based on observations of the lunar crescent after a new moon. In these cases the beginning of the month depends on weather conditions, atmospheric clarity, eye acuity and the location on Earth, since the Moon can generally only be observed about 15 h after new moon and about two degrees above the horizon. These conditions can generally be accurately predicted with about a 30 degree uncertainty in Earth longitude for actual observability. In some cases, predictions are not accepted and observations are required for the determination of the beginning of the month.

Since there are not an integral number of lunar months in a solar year, some calendars (e.g. Hebrew) have introduced intercalated months to adjust the months such that religious holidays occur in the same season each year (see also CALENDAR IN THE MIDDLE EAST AND EUROPE).

There are non-astronomical features to calendars, such as the seven day week. The origin of the seven day week is uncertain, with explanations ranging from weather cycles to Biblical and Talmudic texts. There is also an unproven assumption that the cyclic continuity of the week has been maintained without interruption from its origin in Biblical times.

Calendar in the Middle East and Europe

Calendars are the means for marking the passage of time. Their use can be civil, for the ordering of daily life, or religious, for the marking of observance days, or as a means for noting the rhythm of the seasons for agricultural purposes. Much of calendrical structure is purely arbitrary, such as the length of hours, hours in a day, days in a week and the year within an era. Yet most calendars reflect natural astronomical cycles—the apparent motions of the Sun and Moon and the daily rotation of the Earth. Crude calendars may have been used in neolithic times (see PREHISTORIC ASTRONOMY), but here we consider the development, in historical times, of calendrical ideas of the Middle East and Europe, which culminated in a system used today throughout the world.

Calendars in the Western tradition are rooted in the cyclical motions of the Sun, the Moon or both. The sidereal year measures the time required for the Sun to return to the same place in the sky with respect to the fixed stars. The tropical year is the time from one vernal EQUINOX to the next. The latter is slightly shorter because PRECESSION shifts the equinoctial points westward each year. The key lunar cycle is the synodic period, the passage of the Moon through its phases. When the two are combined as a lunisolar calendar, coordination is more complex. As neither solar nor lunar periods are precise multiples of days, early astronomers were forced to introduce intercalary days at intervals to bring the cycles into line. Otherwise, the months (or years) would slowly slide backwards through the seasons. Because the lunar and solar cycles are incommensurable, no number of synodic months will equal a given number of tropical years, even over very long periods. Nonetheless, they can be equated closely enough to produce a workable calendar.

Ancient calendars

To regulate religious practices, the early Egyptians devised a lunar calendar, inaugurated each year by the heliacal rising of Sirius, i.e. when Sirius appeared briefly in the morning twilight for the first time. For administrative use, they introduced a solar calendar early in the 3rd millennium BC. This system became the basis of our modern one. Assuming a year to have 365 days, they divided it into 12 equal months of 30 days, followed by 5 days at the end. Each month had three 10 day weeks. Being about a quarter-day short of the tropical year, the calendar's initial day slowly slipped backwards, with the new year arriving a day earlier in about 4 yr, but the discrepancy was ignored. The Egyptians also introduced the 24 h day, although the 12 night hours, 10 day hours and 2 dawn–dusk hours were of unequal length. Unequal, seasonal hours remained common throughout the West until the astronomers' equal-hour system spread during the 14th century along with mechanical clocks.

Mesopotamian civilizations developed a lunisolar calendar based on a 7 day week. This length may have symbolized the seven 'planets' (Sun, Moon and five naked-eye planets). Although Mesopotamian astronomers intercalated extra lunar months earlier, it was not until the 4th century BC that the systematic intercalation of seven lunar months over a 19 yr period appeared. This scheme, proposed by the Athenian astronomer METOS about the same time, was later known as the Metonic cycle. Observations showed that, in 19 tropical years, almost exactly 235 lunations occurred. For calculating the dates of new moons, one employed alternating months of 30 and 29 days. After 12 lunations, the total of 354 days was short of the solar year by about 11.25 days. However, these accumulated to more than 33 days after 3 yr, and an extra lunation would be inserted. Thus, 12 yr of 12 lunations, together with 7 yr of 13 lunations, would result in the cycle being brought back to the beginning. The Persian Empire standardized the system, with intercalation in the third, sixth, eighth, eleventh, fourteenth, seventeenth and nineteenth years of a cycle. The Jews and other Middle-Eastern peoples adopted this scheme.

Greek city-states employed a less accurate intercalation scheme, the *octaëteris*, devised in perhaps the 8th century BC. It assumed that eight tropical years are equal to 96 regular plus 3 intercalated lunations averaging 29.5 days. However, having no political unity, Greek cities maintained individual lunisolar calendars, with different start dates and times for intercalating months. Metos, in the 5th century, noted that the tropical year is about 365.25 days. His 19 yr cycle was spread further afield during the Hellenistic period. HIPPARCHUS, in the 2nd century BC, recognized precession and determined very accurate values for both the tropical year and the synodic period.

The Roman republican calendar was less sophisticated than the Babylonian (see BABYLONIAN ASTRONOMY). Based on an older lunar calendar, it had 12 months, some named (*Ianuarius, Februarius, Martius, Aprilis, Maius, Iunius*) and some numbered (*Quintilis, Sextilis, September, October, November, December*). As the year began in March, *Ianuarius and Februarius* were months 11 and 12, respectively. This civil calendar was a day longer than the tropical year and suffered from unsystematic intercalations. By the 1st century BC, the new year fell almost 2 months after the vernal equinox. An 8 day week was fixed by market days, although the 7 day Jewish week became more common in subject territories. Unlike other Mediterranean peoples, the Romans began the day at midnight.

The Julian reform and medieval calendars

Julius Caesar, during his sojourn in Egypt, saw the value of adopting the Egyptian solar calendar and, on the advice of the Alexandrine astronomer Sosigenes, promulgated what is now called the Julian calendar in 46 BC. In this entirely solar calendar, a year was set at 365.25 days. Instead of tacking the five extra days on the end of the year, the Julian calendar distributed the extra days across the year by alternating 31 and 30 day months. The year commenced in January, which had 31 days. Such a distribution would produce a year of 366 days, so one day was removed from

February, which now became 29 days long. To account for the accumulation of an extra day every 4 yr, February was given 30 days during the leap year, the intercalated day usually being inserted after the 24th of the month. Only minor changes were made thereafter: in 44 BC, the month *Quintilis* was re-named *Iulius*, after the assassinated Caesar, and, in 8 BC, Augustus named *Sextilis* after himself, providing it with 31 days. This changed the order of alternation of month lengths, and robbed February of its 29th day. The Augustan adjustments to month lengths survive in modern usage. Augustus, realizing that priests had made every year a leap year since Caesar's time, suppressed all leap years until AD 8.

The Julian calendar, like its Egyptian model, had the value of simplicity. The difference between the Julian and tropical years was sufficiently small that the difference accumulated slowly. As the official calendar of the Roman Empire, the Julian scheme was in force from the Middle East to Scotland; when the Christian church became the dominant religion within the empire, the calendar's survival was assured.

The pre-exilic Jewish calendar was lunar, although little is known about it. After the Babylonian conquest of Israel, the Jewish calendar, like other Semitic calendars, became lunisolar, each year having 12 alternating months of 29 and 30 days. After changes in the 2nd and 3rd centuries AD, it followed the Metonic cycle, with intercalations made according to the Babylonian order. The year began with the autumnal equinox—before the Babylonian exile it began with the vernal equinox—with 7 day weeks, beginning at sundown on Friday. Months commenced with the first sighting of the new crescent Moon; in practice the astronomically calculated time had been used by some Jewish communities from the 3rd century. Days began at sundown, although officially they begin at 6.00 pm in modern practice, with the week commencing on the Sabbath (Friday evening). Following Babylonian tradition, each of the 24 hours in a day is divided into 1080 units based on sexagesimal reckoning. Years are counted from the beginning of the world (*anno mundi*, or 3761 BC).

The Islamic calendar had a common origin with the Jewish and Christian calendars except that it dropped the link to the tropical year. Twelve lunar months of 29 and 30 days alternate. Being strictly lunar (not lunisolar), there are no intercalated months—although an intercalated day may be added to a given year—so that religious observances, such as Ramadan, fall in different seasons over the years, cycling through all the seasons in about 33 years. Like the Jewish, the Islamic calendar has 7 days, each beginning at sundown. The actual visual observation of the new crescent Moon was the start of each lunar month. During the later middle ages, Islamic astronomers developed methods and tables to define the time of the new moon for different locations and when the Moon was obscured by cloud (see also ISLAMIC ASTRONOMY). For civil purposes, the Ottoman Empire adopted the Julian calendar in the 17th century, with Turkey moving to the Gregorian system in the 20th. Most Islamic countries now use the Gregorian calendar for civil purposes, but also employ the era dating from Mohammed's flight to Medina (AD 622).

While the Romans even before the Julian reform began their year at 1 January, only the western part of the empire followed suit. The Byzantine empire moved to 1 September. Early medieval Christians of the West could not agree on an inaugural date. In England and France, Christmas day was the new year; in other areas, 25 March, or even Easter (which was a movable date) took precedence. By the late middle ages, 1 January regained its status.

The Jewish 7 day week, adopted by early Christians, did not become legally binding in the Roman Empire until the time of Constantine (AD 321). Although the Church attempted to suppress the Roman month names—replacing *dies Saturni* with *sabbata* and *dies soli* with *domenicus*, for example—older names persisted in northern Europe. In the counting of days of the month, there was also confusion. The Roman republican method of beginning a month with the *kalends*, followed several days later by *nones* and *ides* and numbering days backwards in relation to these three fixed days, survived in some areas until the 15th century, when successive numbering of days became general.

Because the Julian calendar employed a longer tropical year than actually occurs, the date of the vernal equinox slowly moved backwards. For the Christian Church, this created a problem in setting the date for Easter. Being tied to the Jewish Passover, itself based on the lunisolar calendar, Easter was difficult to fix. The Council of Nicaea (AD 325) set 21 March as the date of the vernal equinox, and adopted the Metonic cycle. Dionysius Exiguus, in the 6th century, provided a rule for setting Easter: it would occur on the first Sunday following the first full moon after the vernal equinox. Should the full moon fall on a Sunday, Easter was deferred to the following week. These complications gave rise a calendrical literature, the *computus*, to which Bede, in the early 8th century, was a notable earlier contributor.

The common scheme was to intercalate 30 day leap months into a 19 yr cycle using the same scheme as the Jewish calendar. Over a 19 yr period, the Julian calendar accumulated 6939 days 18 h, while the lunar cycle accumulated 6940 days 18 h. To bring the two into synchronicity, a day was dropped (the *saltus lunae*), usually in the last month of the cycle. Ensuring that Easter fell on a Sunday and to know when it would occur were more complex. Bede and others introduced a perpetual calendar based on compound cycles, golden numbers and epacts. With such a scheme, tables could be drawn up well in advance to calculate Easter dates.

Agreement on an era for dating was longer in coming. Many ancient countries based their eras on regnal years or years of high officials' tenure. Some Greek cities followed olympiads. In imperial times, the Romans utilized both regnal years and the year since the foundation of Rome

(*ab urbe condita*). The foundation of the Christian era (*anno Domini*) was suggested by Dionysius Exiguus in the 6th century. Trying to solve the Easter-reckoning issue, Dionysius adopted the Victorian period (devised by Victorinus of Aquitaine in the 5th century), which multiplied the 19 yr Metonic cycle by a 28 yr solar cycle to obtain a 532 yr cycle. He then calculated Christ's birth year, from which the first 532 yr cycle would commence. This he believed to be 753 AUC. The English, under the influence of Bede, adopted the Christian era for ecclesiastical purposes in the 7th century, but it was not generally accepted in Europe until the 11th century.

Calendar reform

By the time of Roger Bacon in the 13th century, it was clear that paschal full moons did not fall on their computed dates. Once precession was widely understood, and better tables, particularly the Alfonsine tables of the later 13th century, were available, the pressure for calendar reform grew. Despite a variety of proposals, it was only in the papal reign of Gregory XIII that a revised system, devised by Aloisio Lilio, was promulgated in 1582. The Alfonsine length of the tropical year, being just more than 10.5 min shorter than the Julian year, meant that one would need to drop a day every 134 yr. The papal commission recommended following the Julian leap-year arrangement but suppressing leap years in century years (such as 1900) that are not divisible by 400. The Gregorian reform also adjusted the system for Easter reckoning. As the date of the vernal equinox had slid backwards some 10 days from 21 March over the intervening centuries, Gregory decreed that 5 October 1582 would be followed by 15 October. Catholic countries adopted the system within the first 5 yr; it was accepted in most Protestant nations by the 18th century, such as Britain in 1752. As the Eastern Orthodox Church has never accepted the reform, eastern European countries delayed adoption until the 20th century, such as Revolutionary Russia in 1918 and Greece in 1923. Some Asian and Muslim countries also adopted the system in the late 19th and early 20th centuries.

For a brief period (1793–1805), revolutionary France instituted a calendar based upon the ancient Egyptian solar calendar to remove any religious connotations. Twelve 30 day months were followed by five days of holidays, inserted into early July; a revised leap-year scheme was modified from the Gregorian. Like the Egyptian calendar, three 10 day weeks made up each month. Months themselves were renamed to reflect seasonal weather and activities. As the beginning dates of the months were out of step with the rest of Europe, problems multiplied and Napoleon I returned the country to the Gregorian system.

Since the 19th century, a variety of calendar reform proposals have been made, particularly to solve the problem of months of unequal days. The International Fixed Calendar would provide 13 months of 28 days each, plus one unnamed day to equal 365; a leap-year day would be added each fourth year. The advantage to this scheme is that all months begin on Sunday and end on Saturday. An alternative, the World Calendar, would have four 91 day quarters, each beginning on a Sunday, with months following a 31, 30 and 30 day pattern. A world day would be added after 30 December, plus an additional world day for leap years. Both have advantages, but neither they nor others have elicited much official enthusiasm.

While many cultures over the past few thousand years have devised calendars based on astronomical phenomena, the hybrid formed from the Babylonian–Jewish tradition and the Egyptian–Roman tradition has become the dominant calendrical system world wide. While it cannot be precisely accurate, given the incommensurability of lunar and solar periods, it is entirely sufficient for political and economic needs. Calendar reform, if it does occur, is most likely to be a rationalization of the existing system rather than a wholesale change in structure.

California Nebula (NGC 1499)

An emission nebula in the constellation Perseus, position RA $4^{\mathrm{h}}\,00.7^{\mathrm{m}}$, dec. $+36^{\circ}\,37'$, whose shape resembles the US state of California. The nebula is large (about $2\frac{1}{2}^{\circ}$ by $\frac{2}{3}^{\circ}$), but of low surface brightness. It is illuminated by the star ξ Persei.

Callippus of Cyzicus (*c*. 370–*c*. 310 BC)

Greek philosopher, born in Cyzicus, Asia Minor (now Turkey), a younger contemporary of EUDOXUS, who added more spheres to Eudoxus' nests of spheres to account better for the non-uniformities of planetary motion. The Sun, Moon, Mercury, Venus and Mars each had five spheres while Jupiter and Saturn had four and the stars had one. This increased the accuracy of the theory while preserving the belief that the heavenly bodies moved in circles. Worked with ARISTOTLE. Determined the lengths of the seasons. Constructed a 76 year cycle (the Callippic period) as a more accurate version (four cycles) of the 19 year Metonic cycle, the length of time in which the lunar and solar calendars come back into the same synchronism and by which lunar eclipses can be predicted.

Callisto

Callisto, the outermost of the Galilean satellites (see JUPITER: SATELLITES), is approximately 38% larger in diameter than Earth's Moon (Callisto's radius is 2410 km and the radius of the Moon is 1738 km). However, Callisto's lower mass, surface gravity and higher albedo reflect its ice–rock composition. Callisto's surface is thought to consist of a mixture of ice and dust or rocky materials. Callisto's cratered terrain can be divided into irregularly shaped subunits based on ALBEDO, which vary by a factor of two between units. Several subunits are seen to be relatively smooth and lack impact craters at VOYAGER resolutions; these areas have been interpreted to be regions of possible volcanic resurfacing. However, GALILEO MISSION data which have targeted these regions show that the smoothness is due to surface degradation rather than icy volcanism. Early global tectonism has been suggested to explain the presence of parallel and radial sets of lineaments. Whether or not Callisto is differentiated could not be determined from Voyager data. Galileo images of Callisto's surface do not provide clear evidence of DIFFERENTIATION or the presence of a subsurface liquid water ocean. There is a lack of clear geological evidence of any endogenic modification of Callisto's surface.

Prior to the Galileo mission scientists believed that the surface of Callisto would be heavily cratered at all scales. However, the surface of Callisto is seen in moderate- to high-resolution Galileo images to be smooth and slightly undulate, containing a low spatial density of small (<10 km/pixel) impact CRATERS (see figure 1). The wide spatial distribution of this smooth texture suggests that the smoothing process(es) are global in extent. The dark non-ice material that appears to blanket the surface may become concentrated by the loss of volatile materials during impact events, magnetospheric bombardment and/or via sublimation. This material may also be distributed by impact events and micrometeorite bombardment resulting in the infilling of low-lying topography. Electrostatic levitation or other mechanisms might further contribute to the mobilization of Callisto's dark material.

Impact craters on Callisto exhibit a range of size and degradation states, from fresh with clearly defined ejecta blankets to craters that are barely distinguishable. Mass wasting of crater walls appears to be a predominant process in this degradation. Deposits within craters that appear to be the result of inward debris slides are prevalent. Several of these debris flows originate on the west-facing walls of geologically recent craters. This may indicate a steepening of the crater wall, perhaps by sublimation, that results in a reduction of its stability. Subsequent collapse may be triggered by seismic energy from a nearby impact, or eventual oversteepening of the wall leading to gravitational collapse. This ongoing sublimation erosion and mass wasting best explains the preferential sun-facing rim retreat and crater-wall erosion seen in Galileo images, contributing to the progressive infilling of craters on Callisto's surface.

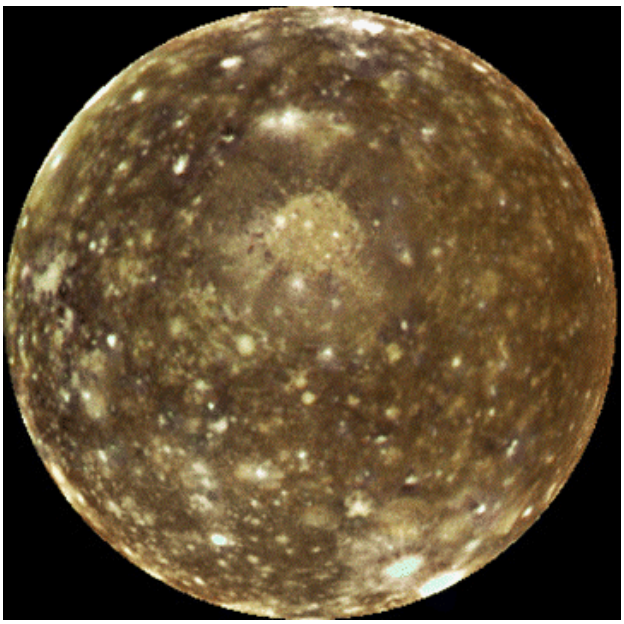

Figure 1. Callisto.

Voyager images show that Callisto's surface lacks significant topography and is heavily cratered. Deficiencies in large (greater than 60 km diameter) impact craters compared with the Moon and terrestrial planets have been identified in Voyager data. However, additional large impact structures that are highly degraded have been identified in Galileo images.

Moderate resolution (0.4–1.1 km/pixel) Galileo images show more detailed structural features within three of Callisto's multiring systems (interpreted to be large impact features) than seen in Voyager data. The youngest, Valhalla, is characterized by bright central plains surrounded by discontinuous, concentric, arcuate structures (troughs and outward-facing scarps). The Asgard multiring system consists of a bright central plains unit surrounded by several discontinuous rings consisting of troughs, but lacks outward-facing scarps. The brightness of Asgard's central plains is enhanced by the presence of a more recent impact crater, Doh, which excavated icier (brighter) subsurface materials. High-resolution images of Asgard reveal fractures within and adjacent to the innermost ring. These fractures are probably the result of the impact-related rifting of Callisto's brittle outer layer. The proximity of these fractures (seen in the innermost ring only) to the impact crater Doh may indicate that these fractures were reactivated by the more recent impact event. The well-preserved outer troughs associated with Asgard have a lower albedo than the surrounding cratered plains.

Adlinda, the oldest of these three multiring structures, lacks a bright central plains unit. However, low-albedo concentric rings, which are more resistant to degradation, are visible. The detailed morphology of Adlinda is obscured by numerous impacts, as well as ejecta from Lofn, a nearby impact crater.

The Near Infrared Mapping Spectrometer (NIMS) on the Galileo spacecraft provided up to 408-channel spectra of Callisto's surface, from 0.7 to 5.2 μm at spatial resolutions ranging from one to hundreds of kilometers per picture element. Regions with strong water-ice absorption features in NIMS spectra usually correspond to bright features (e.g. fresh impact crater deposits) in clear-filter Galileo images. Weak absorption features near 3.88, 4.05, 4.25 and 4.57 μm are interpreted to be due to the presence of an S–H bond, SO_2, CO_2 and organic compounds (e.g. tholins) respectively. In general, correlations between these compounds and surficial geology are complex and poorly understood at present. Globally, the 4.25 μm absorption is stronger on Callisto's trailing hemisphere, while the 4.05 and 4.57 μm absorptions are stronger on the leading hemisphere. In addition to providing insights into surface-material compositions and their distributions, analysis of NIMS data has revealed the presence of a tenuous (surface = 7.5×10^{-12} bar) carbon dioxide atmosphere extending approximately 100 km above the surface. Based on models of CO_2 removal rates, the estimated lifetime of Callisto's atmosphere is about 4 years. Consequently, either this atmosphere is a transient phenomenon, or some process(es) is currently supplying carbon dioxide to the atmosphere.

Like GANYMEDE, Callisto is known as an icy satellite because its relatively low mean density (1836 kg m^{-3}) requires that it is made of about equal amounts, by mass, of ice and rock-metal. Callisto is only slightly smaller than Ganymede, but differs from it in a number of striking ways. Though the mean density of Callisto and Ganymede are similar, Callisto has a larger normalized axial moment of inertia $C/(MR^2)(C/(MR^2) = 0.359 \pm 0.005$, C is the axial moment of inertia, M is the satellite's mass and R is the moon's radius, known from radio Doppler measurements by the Galileo spacecraft), implying a very different interior structure for Callisto compared with the interior of Ganymede. Unlike Ganymede, Callisto is only partially differentiated and consists of a water-ice–liquid shell less than 350 km thick surrounding an essentially undifferentiated ice–rock–metal core. The rock and ice in Callisto are not completely separated and Callisto may not have a central metallic core. The gravitational data obtained by the Galileo spacecraft in a flyby past Callisto do not rule out the existence of a small metallic core in Callisto with a radius less than about 25% of the satellite's radius. However, geophysical arguments and other properties of Callisto make the existence of a small metallic core in the moon unlikely. Consistent with the absence of a metallic core, Callisto does not have an intrinsic magnetic field. The lack of evidence of any endogenic modification of Callisto's surface is consistent with the partial differentiation of only the outer few hundred kilometers of Callisto.

Though Callisto lacks its own magnetic field, the Galileo spacecraft has detected the magnetic perturbation associated with electromagnetic induction in Callisto. Induction occurs when the satellite experiences time periodic changes in the ambient magnetic field of the Jovian magnetosphere due to its orbital motion around Jupiter, the rotation of Jupiter, and the tilt of the Jovian magnetic field (see JUPITER: MAGNETOSPHERE). The magnitude of the electromagnetic induction signal requires that there be a global layer of high electrical conductivity in close proximity to Callisto's surface. The only explanation for such a layer is that it is a subsurface liquid water ocean with a salinity similar to that of terrestrial seawater. Unlike the surface of EUROPA, Callisto's surface provides no hint that a liquid water ocean might hide beneath. The induction signal is the only indirect evidence that Callisto might have a subsurface liquid water ocean. The existence of such an internal ocean in Callisto is difficult to reconcile with the lack of endogenic modification of its surface.

Callisto is not part of the orbital dynamical Laplace resonance of the inner three Galilean satellites (IO, Europa and Ganymede) and it is therefore not tidally heated. Without such a heat source it is difficult to understand how a subsurface liquid water ocean in Callisto could be prevented from freezing solid over geological time. Subsolidus convection controlled by the viscosity of ice is expected to efficiently cool Callisto's interior. At least in the case of Europa, for which there is geological evidence of an internal liquid water ocean in the past or at present, tidal dissipation is a possible source of heat to maintain a subsurface water layer in a liquid state. Tidal heating in the distant past may also explain why Ganymede is completely internally differentiated while Callisto is only partially differentiated. After all, both these moons are comparable in size and mass, have similar amounts of radiogenic heat sources and experienced similar amounts of accretional heating on formation.

Breaking news update (30 April 2002)

A recent image from NASA's Galileo spacecraft adds evidence to a theory that Callisto may hold an underground ocean. The image shows a part of Callisto's surface directly opposite from the Valhalla basin where Callisto was punched by a major collision. The opposition point shows no effect from the impact. Points opposite major impact features on some similar-size worlds, such as Mercury and Earth's Moon, show lumpy terrain attributed to seismic shocks from the distant impacts. The new image is consistent with a 1990s'

Caloris Basin

A large multiringed impact structure on Mercury, centered at 30.5 °N, 170.2 °E. Its official name is Caloris Planitia, which means 'plain of heat'—it was in this region that the highest surface temperatures were recorded by the Mariner 10 probe, which imaged about half of the structure, the other half being in shadow.

Based on the observed half, the Caloris Basin has an estimated diameter of 1340 km. The outer ring is marked by the Caloris Mountains (Montes Caloris), a formation about 100–150 km wide consisting of smooth blocky units 1 or 2 km high and up to 50 km long. Within this ring the floor of the basin is covered with wrinkle ridges and fractures, many of which follow approximately the lines of concentric arcs. Other features are associated with the impact that formed the basin. The mountain ring is punctuated by small plains and secondary craters formed by the fallback of ejecta and impact melt. To the northeast of the basin lies the Van Eyck formation, containing a series of radial features extending for some 1000 km and believed to have been formed by ejecta. At the antipodal point of the impact (the point diametrically opposite, on the other side of Mercury) lies a terrain not seen anywhere else in the solar system: a jumbled, fractured landscape consisting of hills up to 2 km high and 10 km across, and depressions that criss-cross older features. The impact sent seismic surface waves around the planet and compression waves through its core. Where these waves came to a focus at the antipodal point, the crustal rock is calculated to have been shock-fractured and forced 1 km upwards. The present landscape was formed when the upheaval subsided.

The Caloris Basin is estimated to have been formed by the impact of a 150 km object about 3.85 billion years ago, at the end of the period known as late heavy bombardment which marks the last major episode of impact cratering in the early solar system. That it was the last major impact on Mercury is testified by the below average crater density on the basin's floor.

Caltech Submillimeter Observatory

The Caltech Submillimeter Observatory (CSO) operates a Leighton 10.4 m diameter telescope on the summit of Mauna Kea, Hawaii at an elevation of 4200 m. Construction and operations funding is from National Science Foundation grants to the California Institute of Technology. In partnership with the University of Texas and the University of Hawaii, CSO provides the international astronomical community with a state-of-the-art observing facility at submillimeter wavelengths (300–1000 microns), mainly for studies of molecular and atomic lines, and continuum emission from dust in star forming regions in the interstellar medium of the Milky Way and distant galaxies.

For further information see http://www.cso.caltech.edu.

Camelopardalis

(formerly sometimes spelled Camelopardus; the Giraffe; abbrev. Cam, gen. Camelopardalis; area 757 sq. deg.) A northern constellation which lies between Auriga and the north celestial pole, and culminates at midnight in late December. It represents the animal upon which Rebecca rode in Canaan to become the wife of Isaac, and was introduced by the Dutch theologian and geographer Petrus Plancius, who included it on a celestial globe in 1613.

An inconspicuous constellation, the brightest star in Camelopardalis is β Camelopardalis, a wide double star with yellow (G0) and bluish-white (A5) components, magnitudes 4.0 and 7.4, separation 81″. Other interesting objects include the U Geminorum star Z Camelopardalis (range 10.0–14.5, mean period about 22 days) and NGC 1502, an open cluster of about 45 stars fainter than seventh magnitude.

Cameras

Readers of this article are using a natural camera, the human eye. It has a simple lens but phenomenal signal processing which is a study in itself and is not the subject of this article. More relevant examples of cameras are those using photographic film as the detector. Other examples are video cameras that have a CHARGE COUPLED DEVICE (CCD) as the detector.

A telescope is a big camera, but the larger telescopes use a concave mirror for the first optical element instead of a convex lens. Whether a mirror or a lens, this optical element is called the objective. If it is a mirror, it is also called the primary mirror. A telescope system is a series of cameras, the last of which has a detector at its focus. It is sometimes only the last camera that is called the camera.

Figure 1 shows the basic optical design of all telescope systems, in its simplest form consisting of three singlet lenses. Each of these lenses functions as a major component of a telescope system, which on a modern telescope would be more complex than a singlet spherical lens.

Optical aberrations and reflection losses

The rays shown in figure 1 are accurately traced, but the layout is drawn with a larger scale in Y than in X to show the separation of rays more clearly. Obviously, the rays do not come to a sharp focus. SPHERICAL ABERRATION, SA on the drawing, is apparent at the axial focus. The outer rays focus first and are already diverging where other rays come to focus. COMA is also apparent on the drawing in the off-axis image. The ray that passes through the center of the entrance APERTURE, called the chief ray, is laterally displaced from the focal point of the outer rays. The image has the appearance of a comet with the chief ray at its head. It is also apparent that the two foci are not in the same plane, which is an ABERRATION called Petzval curvature. Another aberration is ASTIGMATISM where outer rays perpendicular to the plane of the drawing focus further from the lens, but those rays are not shown. A tutorial on aberrations can be found in the Melles Griot catalog: http://www.mellesgriot.com.

For a given FOCAL LENGTH, spherical aberration is proportional to the cube of the diameter of the aperture. Coma is proportional to the square of the aperture and directly proportional to the field angle. Astigmatism is proportional to the square of the field angle and is directly proportional to the aperture. Axial color is directly proportional to the aperture, whereas lateral color is independent of the aperture and is directly proportional to the field angle.

For a singlet lens, spherical aberration is less if the glass has a high index of refraction, N, because less curvature is needed for a given focal length. However, higher-index glasses usually have a higher dispersion that increases the CHROMATIC ABERRATION.

A single-layer antireflection coating on a lens made of high-index glass has less residual reflectivity at one wavelength, but more average loss than for a low-index glass over a wide wavelength band. Thus a high-index singlet lens is optimum for monochromatic performance, but a low-index, low-dispersion glass is better for a wide spectral region. Another consideration in choice of a glass is radiation darkening and fluorescence.

Optical layout

The first element in figure 1 is labeled the objective. It is shown as a singlet lens, even though such a simple objective has not been used since 1733. The objective is shown focusing beams of light from two stars, each beam consisting of parallel rays, onto the first focal surface. It is said to have positive power because it changes a cylindrical beam of light into a converging cone of light. The rays cross at this first focus, thus the converging cone becomes a diverging cone which is intercepted by a collimator lens which changes the diverging beam back into a parallel, collimated beam. This lens also has positive power but its function is the reverse of the OBJECTIVE LENS. The collimator lens has a shorter focal length than the objective, thus the collimated beam is smaller in diameter than the beam incident onto the objective lens. This lens also produces an image of the entrance aperture (which in figure 1 is at the objective lens). This image is called a pupil. It is also called an aperture stop, or a Lyot stop, if a black plate is located there with a hole equal to the diameter of the beam, to transmit the beam but block unwanted, stray light. The camera lens in figure 1 re-converges the beam to focus onto the detector at the same rate of convergence as at the first focus; thus it has unit magnification. If the focal length of the camera lens were tripled, the magnification, M, would be three times, thus $M = 3$.

The portion of the enormous parallel beam from a star that can enter the telescope is limited by the diameter of the entrance aperture stop, which in figure 1 is at the front surface of the objective lens. This stop is not shown; it is the mechanical structure around the lens. The ray from each star, or object point, that passes through the center of the aperture stop is called the chief ray from that object. Thus, the chief ray also passes through any image of the entrance aperture, such as the pupil between the second and third lenses. Rays that pass though the edges of a lens are called marginal rays.

In figure 1 a marginal ray from the edge of the field intersects the collimator lens far from its center resulting in such a large blur of the pupil and of the final image that is it noticeable on the drawing. If a positive lens were located at the first focus it would move the rays closer to the center of the collimator lens and would move the pupil closer to the collimator lens, but would not change the location of the final focus. Such a lens at an intermediate focus is called a field lens.

It is mostly what is inserted between the second and third lens elements in figure 1 that distinguishes one instrument from another. The inserted device is called a processor. It is sometimes coincident with the pupil but not necessarily.

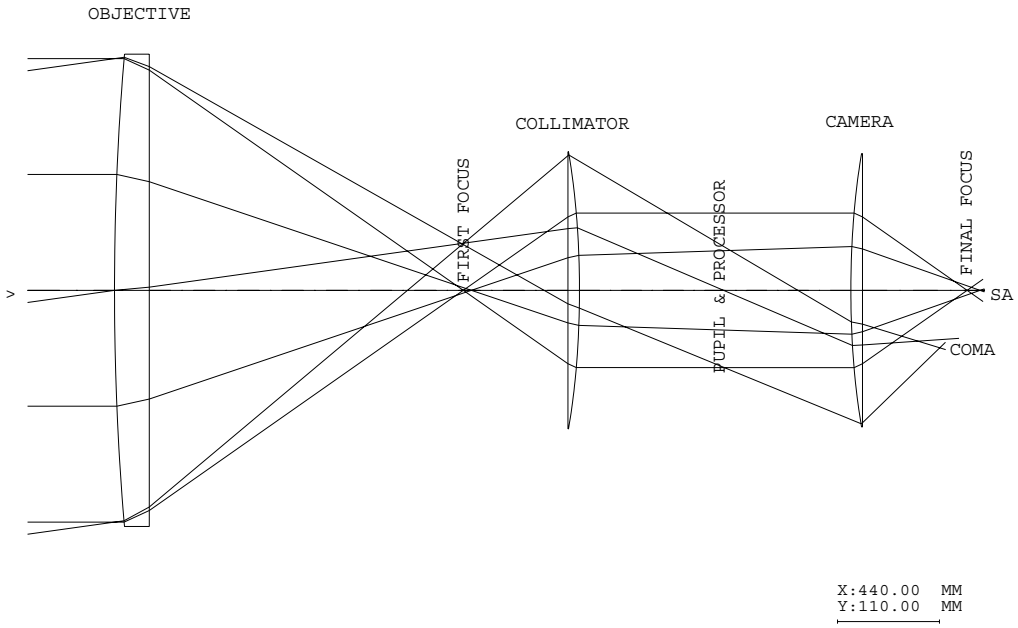

Figure 1. Basic optical layout of all telescope systems.

There are many options for the optical processor, each option producing a different telescope system. Some systems have two or more instruments in series, such as an ADAPTIVE OPTICS module followed by an imaging SPECTROGRAPH.

Some processor options

If the processor is a human eye inserted at the location of the pupil, the camera lens is not needed.

If the processor is a high-quality very flat, thin pair of windows that cause waves of light to add or subtract, the instrument is an INTERFEROMETER. If the processor is a polarizer, such as the N-shaped Wollaston prism, that causes the light waves to oscillate in a single plane, the instrument is a polarimeter (see POLARIMETRY).

If the processor is two N-shaped prisms which can be counter-rotated to increase or decrease the amount of DISPERSION to match that of the atmosphere, the processor is an atmospheric dispersion compensator, ADC.

Often, the processor is a DIFFRACTION GRATING, which changes the direction of the light by a deviation angle, and also disperses the light more or less than the mean deviation angle depending on the wavelength. Because of the deviation, the camera lens must be moved around to intercept the center of the turned beam. If the grating is on a mirror, called a reflectance grating, it would reflect the light back towards the collimator. If reflected straight back onto the collimator, that lens would also serve as the camera lens in an arrangement called a Littrow spectrograph. Usually, the tilt of the grating is chosen so that the reflected beam lies beside the collimator. The camera lens would be rotated around and positioned at that location for this instrument. Also, a field stop would be placed at the first focus in the form of a single, long slit, for a single-slit spectrograph, or by an array of short slits, one on each stellar image, for a multi-object spectrograph, MOS.

If a deformable mirror, a DM, is used instead of a reflectance grating, the system is an adaptive optics module, AOM. Some systems have an AOM and a spectrograph in series, thus there would be a second collimator and camera in the light path, in which case the final focus is the third focus.

If the processor is a simple inverted triangle-shaped prism the beam is turned through a deviation angle but the dispersion is less than from a transmission grating. Therefore, if a transmission grating is bonded to the prism such that the deviation angles cancel, then the beam is not deviated but it is still dispersed. Thus the camera lens does not need to be moved. Such a combination is called a grism, which is usually located before the first focus; thus there can be no slit, the system being called slitless spectroscopy. The surface of the prism that is not bonded to the grating can be curved, and can thus act as a lens, which in the case of the Canada France Hawaii Telescope (CFHT), is part of the prime focus corrector lens near the focus of the primary mirror. This device is sometimes called a grens.

If instead of placing a slit at the location of each stellar image, a fiber is positioned there and bent around to have its exit on the long slit at that focus the result is a fiber-fed multi-object spectrograph. An alternative is to locate an array of small, microlenses or mirrors at the first focus which segments a portion of the field and refocuses each segment along the long slit; such a device is called an image slicer.

More complex objectives

The achromatic lens was invented in 1733 by Chester Moor Hall who used it in a telescope with a 3.5 cm aperture. A positive achromat combines two types of glass in the lens: a convex lens of crown glass combined with a concave lens of flint glass. Flint glass has a higher dispersion than crown glass. A weak flint lens with a concave surface, thus with negative optical power, combined with a convex crown lens with an equal but opposite amount of chromatic aberration, results in a net positive power but with the same focal length at two different wavelengths.

The biconvex and meniscus shapes of the elements serve to reduce spherical aberration to less than that of a singlet lens. (Warning: to have low spherical aberration the achromat must be mounted in the correct orientation with object and image distances close to those for which the lens was optimized.)

Achromatic lenses suffer from secondary chromatic aberration because the focal length at intermediate wavelengths differs from that at pairs of wavelengths where it is the same. The apochromat is a lens with three different glass types. It can have the same focal length at three different wavelengths. It suffers from less secondary (or residual) chromatic aberration than an achromat but it is still noticeable with a large lens.

If in figure 1 a negative lens, which is concave, were added in front of the first focus by a distance equal to its focal length, a collimated beam would be produced, thus this lens would act as an eyepiece. This is the arrangement used in the first telescope by Galileo in 1662. The image quality was very poor.

If the negative lens were moved closer to the focus to one-half of its focal length, the beam exiting from it would no longer be collimated but would converge to focus beyond the first focus by a distance equal to one-half the focal length of the lens. Therefore, the F-number would be doubled thus the magnification would be two times in this example. However, the distance from the objective lens would not be doubled but the effective focal length, EFL, which is the F-number at the focus multiplied by the diameter of the objective lens, would be doubled. Such an arrangement is called a telephoto lens. Its advantage is that it is more compact than if the objective were simply given the longer focal length.

Reflective objectives and space telescopes

Major advantages of using MIRRORS in a telescope are that they are free of chromatic aberrations and need to be optically polished on only one side of the blank.

The telephoto equivalent in a reflecting telescope is to have a convex secondary mirror located before the prime focus of the larger concave primary mirror. Such a two-mirror system is called a classical CASSEGRAIN TELESCOPE if the primary mirror is parabolic, or a Ritchey–Chretien if the primary mirror is hyperbolic. Most large telescopes are of this type.

However, the planned Next Generation Space Telescope, NGST (figure 2) will have a third mirror added following the first focus which forms an image of the pupil in a converging beam which then comes to focus with exceptionally sharp images over a field of view of 6 arcminutes. In order for the beam from the secondary to the tertiary to have clearance to one side of the pupil, the field of view used is restricted to one side of the axis, thus a larger maximum field angle is needed. This increases aberrations, but the three-mirror telescope still has sharper images than a two-mirror telescope (Ritchey–Chretien) and also less field distortion and less curvature of the focal surface. The optical layout of the NGST is shown in figure 2. Compared with a two-mirror telescope, which has a distant exit pupil above the secondary mirror, the NGST has its final pupil much closer to the focus and is thus less telecentric than most telescopes. The purpose of the deformable mirror, DM, on NGST is to compensate for residual imperfections in the figure of the active primary mirror (see SPACE INSTRUMENTATION: NEXT GENERATION SPACE TELESCOPE).

If a space telescope is diffraction limited, then the cameras in the instruments can be smaller and have longer focal lengths than the equivalent on a large ground-based telescope whose resolution is limited by atmospheric turbulence, called SEEING. A spectrograph designed for a small ground-based telescope will work well with a large space-based telescope.

Back-surface mirrors

Large mirrors in telescopes are front-surface mirrors, but for smaller mirrors there are advantages to back-surface mirrors. A common example is a right-angle prism. In that case no metal coating is required because the reflection at the diagonal is by total internal reflection. If the angle of incidence of the light is lower than the critical angle it is necessary to have a reflective coating on the outside of the back surface, such as in a bathroom mirror. This reflective surface can be well protected against corrosion and dust. If the mirror is curved with a shorter radius on the front than on the back, it is called a Mangin mirror. The spherical aberration caused when light passes through the front is balanced by that caused by reflection at the spherical back. It is used as a primary mirror in some small telescopes.

If the glass is made thick and nearly flat but aspherized, the result is called a solid Schmidt camera.

An array of small back-surface mirrors is used in the image position sensor for the adaptive optics system for the WIYN telescope on Kitt Peak. It is described at http://claret.kpno.noao.edu/wiyn/wttm.html.

Also, an image-slicer design option for NGST uses arrays of back-surface micromirrors. An advantage is that a change of temperature changes both the curvatures of the mirrors and their separations so they stay in focus.

Eyepieces

The EYEPIECE is a reversed camera lens but in detail it has a very different task from that of the objective or of a commercial camera lens because of the location of the pupil. In the case of the eyepiece, the pupil must be

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

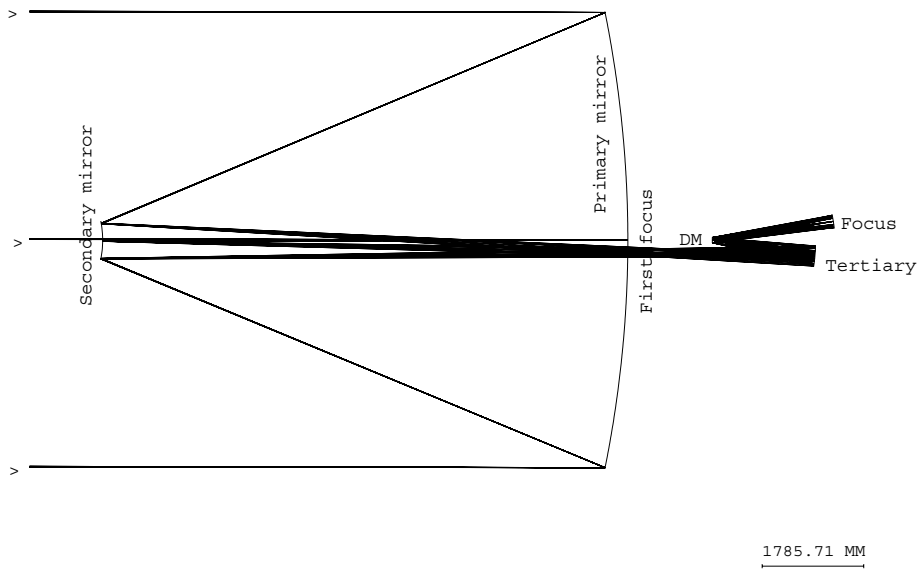

Figure 2. NGST: primary, secondary, tertiary and deformable mirrors.

external to the lens, because it must be on the eye of the beholder, which with eyelashes is 10 to 15 mm from the lens, or 18 to 20 mm if the person wears spectacles. This distance is called EYE RELIEF. Also, the diameter of the EXIT PUPIL should be small enough for all of the beam of light to enter the human eye, whose iris ranges in diameter from 2 to 5 or 8 mm depending on age. Another complication in the optical design of an eyepiece is the increased FIELD OF VIEW that is in inverse proportion to the diameter of the pupil. If the diameter of the telescope is 1 m and if it has a one-third degree field of view, the field of view of the eyepiece with a 5 mm pupil must be 200 times greater, thus 67°, requiring a complicated design with several elements. The required focal length of the eyepiece is directly proportional to the F-number of the focus being viewed, thus is twice as long at an F-20 focus as at an F-10 focus.

Modern computer designed eyepieces have up to eight elements of several glass types and up to an 82° field of view which is more than the eye can take in at once, and gives the impression of being in space. An example of a modern eyepiece, the Erfle, which has five elements, is in figure 3. A description of eyepiece designs is at the Australian web site; http://www.users.bigpond.com/PJIFL/INDEX.html.

Fiber feed

Fibers have the advantage in multi-object spectroscopy of selecting objects from anywhere in the field of view of the telescope and aligning them along the slit of a spectrograph. However, fibers suffer from focal ratio degradation, FRD. This disadvantage is greater on telescopes that produce sharp images, such as space telescopes. FRD is less of a disadvantage on ground-based telescopes where the image quality is already degraded by turbulence in the Earth's atmosphere, or seeing.

Telescope location: Earth or space

Because of atmospheric turbulence, called seeing, the image of a star at the focus of a ground-based telescope system is enlarged, thus a shorter EFL is required to match the sharpness of the image to the resolution of the detector. Thus a faster (smaller) F-number is needed than if the telescope were in space. For a large ground-based telescope, the optical elements are not only very big but also the camera is more complicated, requiring more elements to correct the optical aberrations. Figure 4 shows an outstanding spectrograph camera lens designed by Harland Epps for the Keck 10 m telescope. It has nine elements: a liquid-coupled doublet, a singlet, a liquid-coupled triplet, a doublet and finally a singlet field flattener lens near the focus. Also shown are a filter and a dewar window. The largest element has a diameter of 36 cm and is made of calcium fluoride.

By comparison, if a telescope is in space the minimum size of a stellar image can be limited only by diffraction, and thus is the same size at the focus on the detector whatever the diameter of the telescope, for a given F-number. Thus, for example, a simple spectrograph camera designed for a 1 m telescope would operate at its full efficiency if used with an 8 m space telescope. This makes more feasible the use of efficient spectrographs on giant space telescopes of the future, such as perhaps a 100 m liquid mirror telescope on the Moon.

Diffraction limit

ring, in seconds of arc, is

$$\phi = \frac{\lambda}{2D}$$

for λ in microns and D in meters. For the 8 m NGST, at $\lambda = 2\ \mu$m (near infrared) $\phi = 0.25$ arcsec. The Rayleigh limit is one-half of this amount, 0.125 arcsec, which is the half-width of the Airy disk.

Adaptive and active optics

An active optic cell can bend the mirror it supports to correct for imperfections in the shape of the mirror, such as the primary mirror. By comparison an adaptive optic is a deformable mirror, DM, located closer to (but not at) the focus where the beam is much smaller than at the primary mirror. The DM is rapidly deformable to correct aberrations caused by turbulence in the Earth's atmosphere, and it also corrects wavefront errors caused

by imperfections in the primary mirror. The first non-military adaptive optics system, called Come-on, started operation at the European Southern Observatory in 1989 on the 3.6 m telescope. The newest, improved system is called Adonis. In 1996 the adaptive optics Bonnette, or PUEO, was commissioned on the Canada France Hawaii Telescope, CFHT. These systems are described in http://www.ls.eso.org/lasilla/Telescopes/360cat/adonis/html/aosystem.html#optic and http://cdsweb.u-strasbg.fr:2001/Instruments/Imaging/AOB/performance.html.

An adaptive optics system, like a spectrograph, has a collimator followed by a camera, usually off-axis mirrors to avoid obstruction. Instead of a grating or prism, there is a deformable mirror, DM, between the collimator and the camera. In most systems the collimator and camera mirrors are parabolic, one for the collimator and one for the camera. With only two powered mirrors, the focal surface is curved, but not sufficiently to significantly degrade the resolution of a field diameter of a few arcminutes. Because the beam between the two paraboloids is collimated, the image at the focus on the axis at the center of the field is perfect, whatever the focal lengths of the two paraboloids and whatever the distance at which they cut off the axis of the parent mirrors. The focal surfaces are tilted with respect to the axis of the paraboloids but are not tilted with respect to the axis of the telescope. Thus it is not necessary to tilt the detector when the adaptive optics system is inserted.

It is often required that the camera should have a longer focal length than the collimator to magnify the sharpened images to match the resolution of the detector. In that case, field aberrations (of the center of the field of view) are minimized if the distance of the camera mirror from the axis of the parent mirror surface is increased in proportion to the square of the magnification.

The Gemini adaptive optics system is unusual in that the module available for the adaptive optics system (on a de-rotator needed because the telescope has an alt-azimuth mounting) is further from the focus than the F-number multiplied by the diameter of the DM, thus the camera must be in the form of a reverse telephoto—it must increase the diameter of the beam from the DM before convergence. Thus the Gemini system, called Altair, has two mirrors in the camera, convex then concave, in addition to the collimator mirror, thus it is a type of three-mirror anastigmat, TMA. An advantage of having three mirrors instead of two is that the focal surface is flat, thus the images are sharper on a flat detector. It is described at http://www.dao.nrc.ca/facilities/gemini/altair/altair.html.

The wavefront from a natural guide star is analysed to generate the signal to deform the DM. A sodium laser star in the Earth's atmosphere will also be analysed. Because it is out of focus where the natural star is in focus within the central shadow (of the secondary mirror) in the laser beam, a pinhole mirror permits very efficient separation of the two beams in the Gemini design.

A system at Mount Wilson is the first to use an ultraviolet laser guide star, described at http://www.astro.uiuc.edu/projects/unisis/.

The simplest adaptive optics systems, such as for the WIYN telescope on Kitt Peak, corrects only for jitter of the image, called tip-tilt. Surprisingly, the NGST will have a simple adaptive optics system to correct for jitter of the satellite which is expected to be as much as ± 2.7 arcsec.

Glass catalogs

When a ray of light is incident in air upon a flat piece of glass, the direction of the ray is changed inside the glass. If the angle of incidence, measured with respect to the normal (perpendicular) to the glass surface is α, and the angle after refraction is β, the index of refraction, N, is defined as

$$N = \frac{\sin \alpha}{\sin \beta}.$$

The index of refraction, N, is inversely proportional to the speed of light in the glass compared with the speed in a vacuum. However, it is measured with respect to the speed in air, thus a small correction is needed to the indices listed in glass catalogs if the material is used in a vacuum.

Catalogs list about 250 different types of glass. The oldest manufacturer is Schott in Germany. A more recent supplier is Ohara in Japan (http://www.oharacorp.com/index.html).

Glasses from both manufacturers are used in telescopes. Hoya is another major supplier. Glasses are identified by their index of refraction N_d, at the yellow helium spectral line whose wavelength is 587 nm, and by the difference in N between that of the blue hydrogen line, N_f at 486 nm and the red hydrogen line, N_c at 656 nm, listed as $N_\mathrm{f} - N_\mathrm{c}$ in the catalogs. A third, very important identification is the Abbe value, which combines both the index of refraction and the dispersion,

$$V_\mathrm{d} = \frac{N_\mathrm{d} - 1}{N_\mathrm{f} - N_\mathrm{c}}.$$

Thus a low dispersion glass has a high V_d number. Each glass type has a six digit code number: the first three digits of $N_\mathrm{d} - 1$, followed by the first three digits of V_d. Each glass type is also given a name which differs depending on the manufacturer. For example, the common borosilicate crown (low dispersion) optical glass 517642 is Schott BK7, Ohara S-BSL& and Hoya BSC7. The common flint glass 620364 is Schott F2, Ohara PBM2 and Hoya EF2.

A diagram plotting N_d versus V_d, listed as an $N_\mathrm{d}/V_\mathrm{d}$ diagram, for catalog glasses is available on the web at http://www.schottglasstech.com/. The transmission of catalog glasses depends on type. It is listed for the wavelength region from 0.28 to 2.4 μm, but most of the glasses transmit over only a fraction of that region.

Special materials that transmit further into the ultraviolet and infrared are not included in these catalogs because they are not conventional glasses. Calcium fluoride which is now available in large pieces, transmits

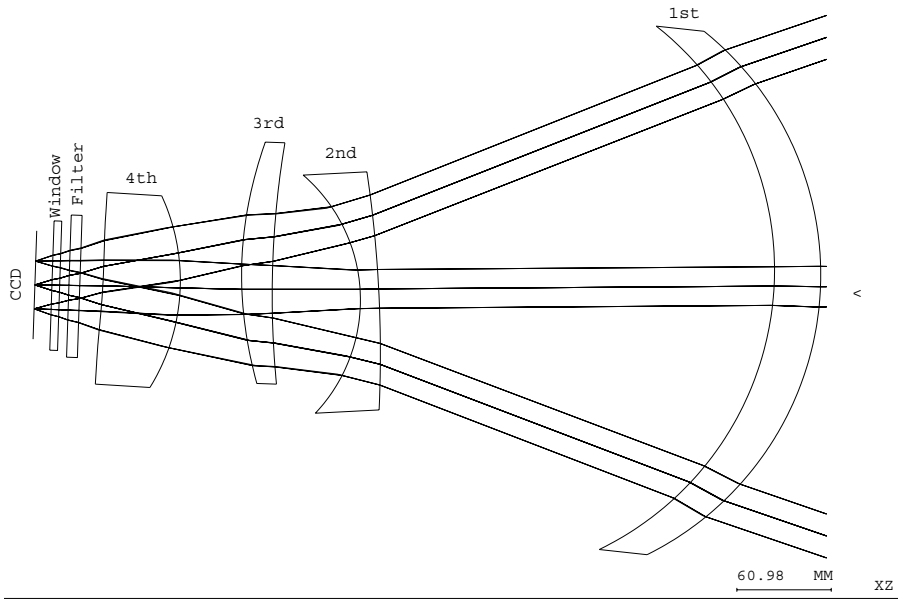

Figure 5. Four-element corrector lens for the Hickson 6 m LMT.

over a much wider wavelength region, from 0.23 to 7.8 μm. It has a very low index of refraction and dispersion: $N_d = 1.4$, $V_d = 96$. Zinc selenide has a very high index of refraction: $N_d = 2.6$, $V_d = 8$.

Correctors for liquid mirror telescopes

By rotating a thin film of mercury a parabolic surface of optical quality is formed serving as the primary mirror of a liquid mirror telescope, LMT. Because of the naturally parabolic shape, images at the center of the field of view are sharp. Several LMTs with diameters ranging from 2.4 to 3 m are operating in North America and a 6 m LMT is being constructed in Canada. Ermanno Borra at Laval, Paul Hickson at UBC and Mark Mulrooney at Cloudcroft Observatory, New Mexico, are instrumental in the development of LMTs.

The 6 m LMT being built at the University of British Columbia will have a very short focal length: 9 m thus $F/1.5$. This fast focal number is achieved without additional cost for the mirror simply by designing its mounting for a higher rate of rotation, and thus permitting a smaller enclosure. However, the short focus increases the difficulty of correcting the coma and astigmatism. The well known corrector lens of the type originated by Ray Wilson in Germany and by the late Charles Wynne in England consists of three lenses: a positive meniscus lens followed by a negative lens and ending with a positive lens near the focus. Referred to as a prime focus corrector lens, they are used on many telescopes. They have a flat focal surface but have considerable pincushion distortion that was not found to be objectionable in the days of photographic detectors. After the development of the CCD permitting much fainter star fields to be imaged it became advantageous to minimize field distortion to simplify the subtraction of background light from the sky. Such correctors have four elements instead of three.

A survey of LMTs around the world is given at http://www.astro.ubc.ca/lmt. These inexpensive telescopes are used for tracking space debris, for aeronomy and for astronomy.

For an LMT there is an additional need to control distortion because the time exposure of moving images on the CCD detector is achieved by time delay integration, TDI, also called drift scanning. With conventional CCDs the electronic readout is at constant rate along each column of pixels, thus the images should move at a constant speed and in straight lines which requires zero field distortion when observing space debris or satellites. However, when observing stars with an LMT that is not located on the equator of the Earth, the rotation of the Earth causes the images to move in a curved path and at a rate that depends on the declination of the object. Fortunately, this sidereal distortion can be removed by an asymmetrical distortion of the corrector achieved by deliberately decentering and tilting the elements of the corrector lens. The layout of such a lens is shown in figure 5 where the elements are positioned for a declination of 49°. For observation of satellites zero distortion is restored by removing the decentering and tilts of the elements. If the telescope were moved to Cloudcroft Observatory at a latitude of 31° the reduced sidereal distortion for that site could be achieved by appropriate repositioning of the elements.

An advantage of drift scanning is that variations in pixel-to-pixel sensitivity of the detector are reduced because the response is averaged over all CCD pixels in a column. Steerable telescopes are sometimes used for drift scanning by tracking along a great circle at a non-sidereal rate and rotating the detector. In this case, nonlinear

effects are minimized without requiring an asymmetrical corrector. However, because of the physical motion required of the camera the length of the great-circle track is limited. The observations would need to be interrupted while the camera position is set to follow different great-circle paths. By comparison, the LMT, or any telescope stopped at the zenith, can integrate continuously with a stationary detector.

Campanella, Tommaso [Giovan Domenico] (1568–1639)

Born in Stilo, Calabria, Italy. A Dominican, he wrote on Telesian philosophy and astrology, and cast flattering horoscopes for the influential. A great admirer of Galileo, in 1622 he published his *Apologia pro Galileo* ('*Defense of Galileo*'), defending the Copernican system and the separate paths of scripture and nature to knowledge of the Creator. He adopted an animistic, yet empirical, interpretation of the world, which influenced a number of followers. Denounced to the Inquisition, he spent nearly half his life in prison in Naples and Rome, sometimes leniently, with a salary and freedom to write, but also under the worst conditions, with torture. In 1634 the Inquisition discovered yet another plot and Campanella was implicated. He fled Rome before he could be arrested, was well received in France, but soon died in Paris.

Campani, Giuseppe (1635–1715)

Italian instrument and clock maker, born in Castel San Felice (near Spoleto), Italy, *fl*. Rome, best known for his optical instruments, primarily telescopes (for which he made the best composite eyepieces available and lenses of longer focal length than any other optician—up to 40 m), but also for microscopes. All JEAN CASSINI's discoveries were made with Campani telescopes, with which Cassini exclusively equipped the Observatory in Paris.

Campanus of Novara [Campano, Giovanni] (1220–96)

Astronomer, mathematician, born in Novara, Italy, chaplain to Pope Urban IV. Wrote *Theorica Planetarum* which describes the construction of a planetarium, the first to be described by a European. The work matches detailed calculations of the positions of the planets to the description of the motion of the mechanism.

Campbell, William Wallace (1862–1938)

Astronomer, born in Hancock County, OH. Trained as an engineer, became director of Lick Observatory, measured stellar radial velocities with the Mills photographic spectrograph (which he designed) and published them (with Joseph Moore) in a catalog (1928). From studies of the Martian atmosphere, he deduced that it could not support life. Founded the Lick southern station in Chile, discovered numerous (339) spectroscopic binaries (including Capella), and determined the motion of the solar system with respect to surrounding stars.

Canada–France–Hawaii Telescope

The Canada–France–Hawaii Telescope (CFHT) is a 3.6 m optical-infrared telescope located on the summit of Mauna Kea on the island of Hawaii. On 20 June 1974, representatives from the National Research Council of Canada (NRC), the Centre National de la Reserche Scientifique of France (CNRS) and the University of Hawaii (UH) signed the Tripartite Agreement that culminated in the dedication of the facility on 28 September 1979. Time is allocated to the partners in proportion to their financial support, with Canada and France each receiving 42.5% of the time. The Observatory headquarters is located in the town of Waimea and houses approximately 50 people.

The telescope has interchangeable top-ends supporting prime-focus ($f/4$), Cassegrain ($f/8$ and $f/35$ IR) and Coudé foci with a large complement of imaging and spectroscopic instruments.

The CFHT has pioneered much of the methodology used to enhance image quality on ground-based telescopes. This began with dome environment control, through to the first operational tip-tilt wave-front correction system (1988), and the deployment of a facility adaptive optics system in 1996. More recently, CFHT has implemented a wide-field imaging plan. It operates CFH12K, the largest close-packed CCD mosiac camera in the world and will deploy a full square-degree CCD camera in mid-2001.

Canadian Astronomy

Canada is big (second only to Russia in area) and sparsely populated (30 million). These facts, as trite as they are, do explain a lot about the country, even its scientific endeavors. Almost all astronomy carried out in Canada during centuries of exploration prior to 1900 was connected with surveying and time-keeping. Even the efforts by Sandford Fleming to introduce worldwide time zones in the 1880s seem appropriate in a country which spans nearly 90° in longitude. Some 20th century examples are C S Beals' identification of dozens of ancient meteorite craters in the Precambrian Canadian shield, the launching of the communications satellite Alouette I in 1962 (Canada was the third country in the world to build a satellite) and the pioneering work in long-baseline radio astronomy whereby two Canadian radio telescopes separated by thousands of kilometers were linked in 1967.

Another cliché of life in Canada is the cultural and economic dominance of its giant neighbor, the United States. Some of America's best-known astronomers of the 19th century, including SIMON NEWCOMB, were born in Canada but went south to the land of opportunity. The 'brain drain' is still a concern today. In fact the Natural Sciences and Engineering Research Council (NSERC), the government-supported granting agency, has programs to encourage bright young scientists to study and work in Canada.

Finally, it should be recognized that Canada is officially bilingual. This means that all federal services are available in both French and English. It also explains why some acronyms such as CASCA (Canadian Astronomical Society/Société canadienne d'astronomie) reflect this dual character. In practice, among institutions where astronomy is taught, the Universités de Montréal and Laval in Québec operate in French, the Universities of Moncton in New Brunswick and Laurentian in Ontario use both official languages and the rest are English language based.

Early history

Very little has been written about aboriginal astronomical traditions in Canada except for a recent book, *The Arctic Sky*, by John MacDonald, which explores the knowledge of the Inuit people of the far north. It was also in the Arctic that European astronomy first touched Canadian shores. English explorers intent on a northwest passage to the orient looked to the Sun, Moon and stars to fix their latitude and longitude. The best pre-telescopic results were achieved by Thomas James who wintered in 1632 in the bay which now bears his name. However, it was the Jesuit missionaries from France, who often spent the best part of their lives here, who really introduced astronomy in Canada. They too were concerned with geographic position and to that end observed eclipses. The most accurate of these was a lunar eclipse observation on 30 January 1646, made by Father Joseph Bressani using a small telescope at a remote mission near present-day Midland, Ontario. The missionaries at Quebec recorded positions of the bright comets of the 1660s and about the same time they, along with some lay teachers, began teaching surveying, navigation and hydrography.

The tradition of practical astronomy as the basis of mapping continued after the capture of Quebec by the British in 1759 both in the Atlantic region and in the vast western territories of the Hudson's Bay Company. Scientifically significant were the transit of Venus in 1761, observed in Newfoundland by John Winthrop from Massachusetts, and the 1769 transit observed by surveyor Samuel Holland and his assistant at two locations in Quebec and on behalf of the Royal Society by William Wales at Fort Churchill on the shores of Hudson Bay. On Wales' advice, the Company appointed its first surveyor, Philip Turnor, who mapped much of western Canada along with two younger men, Thompson and Fidler, to whom he taught the procedures of practical astronomy while they were stationed at Cumberland House, Saskatchewan.

Eastern Canada became more settled following the arrival of Loyalists from the newly independent United States. In 1789, they founded the first English-speaking institution of higher learning at Windsor, Nova Scotia, naming it King's College. Although several other universities have their origin in the early 19th century, the first to be equipped with an observatory and to offer lectures in astronomy was at Fredericton, New Brunswick, in the 1850s. Other early observatories include the Toronto Observatory (originally a magnetic observatory, opened in 1840), Charles Smallwood's private observatory near Montreal, equipped with a 18 cm Fraunhofer refractor in the late 1840s, and observatories with 15 cm refractors at Quebec and Kingston established in the 1850s.

By 1867, when four colonies formed the new Dominion of Canada, some interest in 'pure' astronomy had begun to emerge, although preoccupation with the very real needs of surveying and time-keeping continued. Reverend Bolduc at the Quebec Seminary taught astronomy and had at his disposal a 40 cm Foucault reflector, and astronomy was part of the curriculum at Queen's University, Kingston, and at King's College, Windsor, Nova Scotia. E H Ashe, of the Quebec Observatory, traveled to Iowa to study and photograph the solar eclipse of August 1869. Smallwood, in Montreal, wrote on lunar and solar phenomena. One event which ultimately had lasting significance was the formation of the Toronto Astronomical Club in 1868 by a little group of amateurs. In the 1880s, one of their number was observing spectra of the Sun and stars, some were taking photographs of the Sun and Moon and others still were observing and sketching surface features on the planets. By 1890, they had incorporated as a Society and began publishing transactions which were distributed to universities and observatories around the world. This group evolved into the ROYAL ASTRONOMICAL SOCIETY OF CANADA (RASC), whose *Journal* still remains the only

national publication for Canadian astronomical research and news.

One of the members of this group in the 1890s was a young physics professor at the University of Toronto (U of T), C A Chant, who had the foresight to ally astronomy at the university with physics. W F King, who had worked on the 49th parallel boundary survey in the 1870s and who rose to the position of Canada's first 'Chief Astronomer' in 1890, also recognized that research was expanding beyond the traditional fields of time and position. So it came about in the early years of the 20th century that a substantial government observatory was founded in the nation's capital, Ottawa, and a separate Astronomy Department was established at U of T. Although positional astronomy and geophysics were the backbone of the program at the Dominion Observatory (DO) when it opened in 1905, its main instrument was a 38 cm Brashear refractor and its staff for many years were mostly graduates of the U of T.

The growth of the profession 1905–1970

Astrophysical research at a national observatory was unusual and might not have occurred at Ottawa if there had been any universities in the country with suitable facilities. However, there were not, and it was recognized that the Observatory would provide a stimulus to science throughout the Dominion. It is a role which government still plays in Canadian astronomy since many smaller institutions cannot on their own afford the facilities necessary for modern research.

Solar studies and stellar spectroscopy were the main areas of research in astrophysics at the DO but it soon became apparent that the scope of a 38 cm instrument in a less-than-desirable environment was limited. The main push for improved facilities came from J S PLASKETT, who had graduated as a mature student from Toronto and had joined the staff of the DO even before it opened. By 1910 he realized 'that our output in radial velocities observations of spectroscopic binaries is likely to diminish materially. . . . The only remedy is an increase of telescope aperture'. It is a tribute to his organizational and political genius that, in spite of the First World War, the DOMINION ASTROPHYSICAL OBSERVATORY (DAO) equipped with a 1.8 m reflector opened near Victoria, British Columbia, in April 1918. At the time, it was the largest operating telescope in the world since the Mount Wilson 2.5 m was was still undergoing modifications. The DAO is still going strong—a second telescope, a 1.2 m with a Coudé spectrograph, was added in 1961 and detection equipment in both instruments has been continuously updated. Spectroscopy has always been the cornerstone of the DAO programs, with some highlights being Plaskett's work on the rotation of the Galaxy using radial velocities of O- and B-type stars, McKellar's work on interstellar absorption, Petrie's calibration of the absolute magnitudes of B stars and Batten's catalogues of spectroscopic binary orbits.

An even larger reflecting telescope (1.9 m) began operations in 1935 thanks to the persistence of Dr Chant at the U of T and the very generous private donation of the DAVID DUNLAP OBSERVATORY (DDO). It was the only major astronomical facility at a Canadian university for many years, and U of T was the only place in the country where a student could get specialized training in astronomy until the 1950s. Spectroscopy and photometry have been the basis of most of the research carried out there with HELEN HOGG's lifelong work on variable stars in globular clusters and Bolton's convincing 1972 research on Cygnus X-1 as a black hole being especially memorable.

After the Second World War, radio astronomy opened up. In Canada it was an offshoot of radar work carried out by A E Covington at the NATIONAL RESEARCH COUNCIL (NRC). He recognized the potential of some of the equipment for solar research and in 1945 began a program of monitoring the Sun at a wavelength of 10.7 cm—a program which still continues. Two large steerable radio telescopes were inaugurated in the 1960s—one being the 45 m at the ALGONQUIN RADIO OBSERVATORY (now used for geodetic measurements) and the other a 26 m dish at the DOMINION RADIO ASTROPHYSICAL OBSERVATORY (DRAO) at Penticton, British Columbia. These instruments proved very versatile in studying the interstellar medium and in identifying some of the largest molecules in space. By 1966, the DRAO also had installed two large interferometric arrays used for high-resolution imaging of discrete sources and mapping of the galactic plane.

Because of the postwar baby boom and the cold war space competition, the 1960s saw a tremendous surge in the founding of universities, some with astronomy departments or parts of departments. In fact a third of all Canadian universities were established in the 1960s. The first astronomy PhD was earned in Canada in 1953 at the U of T; 20 yr later, there were 12 awarded at seven different universities. During this period, the dissertations covered a wide range of topics but there was a preference for stellar structure and evolution as well as radial velocities applied to studies of intrinsic variables and space motions of stars in the Galaxy.

Recent developments, present status and plans for the future

By 1970, the old Dominion Observatory had outlived its usefulness, so it was closed and all government astronomical research programs were placed under the aegis of NRC. At the time this meant some programs like meteor studies which had been the life work of Peter Millman continued in Ottawa, but most of the astronomy was centered in British Columbia at the DAO and DRAO. In 1971, one of NRC's distinguished staff scientists, GERHARD HERZBERG, won the Nobel Prize in Chemistry for 'his contributions to the knowledge of electronic structure and geometry of molecules, particularly free radicals'. NRC formed the HERZBERG INSTITUTE OF ASTROPHYSICS (HIA) in his honor in 1975.

It was not only in government that a reorganization occurred. With a larger scientific community to draw on, the professional society, CASCA, was formed in 1971 and

Table 1. The main Canadian universities with research programs and PhD programs in astronomy and astrophysics.

Name (and city in order east to west)	Approximate number of PhDs in last 10 yr	Telescopes ≥0.5 m (type or observatory name)	Some areas of research
Laval (Quebec)	11	1.6 m Mont Mégantic	Cosmology, galaxies, interstellar medium, white dwarfs, massive stars
Montréal	21	1.6 m Mont Mégantic	
Queen's (Kingston)	11		Solar system dynamics, star formation, interstellar medium, star clusters, galaxy structure and formation, neutrino and particle astrophysics, cosmology and general relativity
Toronto	37	0.6, 1.9 m at DDO David Dunlap observatory 0.6 m H S Hogg[a]	Stellar astrophysics, contact binary systems, variables, nebulae, interstellar matter, cosmology, galaxy clusters and evolution
York (Toronto)	6	0.6 m	Dynamics of solar system and star clusters, planetary atmospheres, nebular, supernova remnants, pulsars, active galactic nuclei
McMaster (Hamilton)	10		Stellar populations, globular cluster systems, star-forming regions, theoretical astrophysics
Waterloo/Guelph	9	Bakos Observatory	Molecular astronomy, interstellar medium, star formation, galactic structure, cosmology, gravitation, laboratory astronomy, instrumentation
Western Ontario (London)	5	1.2 m Elginfield Observatory	Stellar rotation, atmospheres, magnetic fields, surface features, interstellar matter and nebulae, star clusters, quasars
Alberta (Edmonton)	11	0.5 m Devon Observatory	Photometry and spectroscopy of binaries and variables, supernova remnants, cosmology
Calgary	11	0.5 m Rothney Observatory 1.8 m Honeycomb	Monitors asteroids and variable stars; planetary transit searches, optical and infrared photometry and spectroscopy, continuous monitoring of circumpolar objects
British Columbia (Vancouver)	19	2.7 m liquid mirror	Low-mass stars, substellar companions, astroseismology, atmospheres of hot stars, galaxy interactions
Victoria	15	0.5 m Climenhaga Observatory	Formation, structure and evolution of solar system objects, stars, galaxies, galaxy clusters, quasars and large-scale structure

[a] Helen Sawyer Hogg Telescope is located in Argentina.

by its first annual meeting had 145 members. Currently there are 381 members, 281 of whom are located in Canada. The fact that more than a quarter of the members live abroad is mainly due to emigration.

Multi-user scientific facilities and international cooperation became the only way that Canada could afford to participate in large projects at the forefront of current research. The MÉGANTIC ASTRONOMICAL OBSERVATORY, opened in 1978, is jointly run by the Université de Montréal and Université Laval. HIA is responsible for Canada's share in three international ventures—the 3.8 m CANADA–FRANCE–HAWAII TELESCOPE (CFHT) which opened in 1979 and in which Canada has a 42.5% interest and more recently the 15 m JAMES CLERK MAXWELL TELESCOPE (25%) also in Hawaii and the 8 m GEMINI OBSERVATORY telescopes (14%) in Hawaii and Chile. All three facilities have permanent staff employed by HIA but time allocation is made widely available. In addition, HIA continues its responsibility for the two Canadian observatories already alluded to—DRAO, now a major collaborator in the Canadian Galactic Plane Survey (see figure 1) and DAO, which now is home to the Canadian Astronomy Data Center, a distribution center for data from the Hubble Space Telescope and an archival center for data from CFHT. Two other recent Canadian multi-user projects are the Canadian Institute for Theoretical Astrophysics (CITA), located at the University of Toronto, and the Sudbury Neutrino Observatory (SNO), a collaborative project of several Canadian and American universities.

From 1984 onwards, financial cutbacks were the order of the day. Science budgets and astronomy funding in particular declined at the same time as international cooperative ventures used up larger proportions of what was available. Throughout the 1990s, research grants provided by NSERC in space and astronomy amounted to only about $4 million per year.

There are now about 35 Canadian institutions of higher learning where some astronomy is taught; in about half of these research is done and doctoral degrees are offered in astronomy or closely related fields (the main ones are listed in table 1). Approximately 20 PhDs are awarded each year, the most prevalent topics being

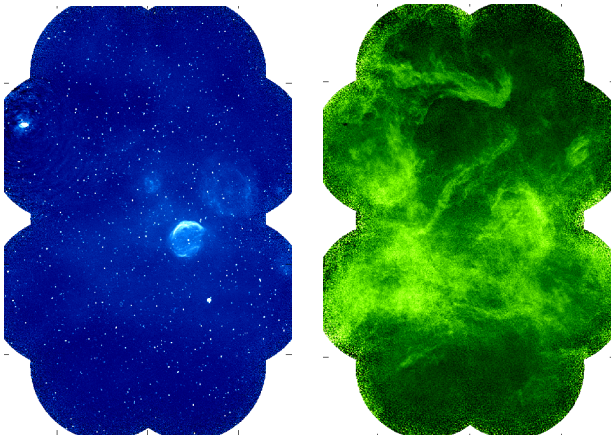

Figure 1. Images from the Canadian Galactic Plane Survey of a $6.8^\circ \times 9.7^\circ$ region in Cassiopeia. Left: 21 cm continuum; right: 21 cm line.

theoretical astrophysics, structure and evolution of normal galaxies, clusters of galaxies, cosmology, interstellar matter and the stellar environment. Greater participation in theoretical work ranging from cosmology to planetary system dynamics in recent years is partly a reflection of the establishment of CITA.

Building on technical expertise that Canadians already have in such areas as instrument and software design, a partnership among NRC, NSERC and CASCA is developing a long-range plan for astronomy in Canada until 2015. At the present time this panel is considering a wide variety of issues, including maintenance of present programs and facilities along with participation in the Next Generation Space Telescope, the Atacama Large Millimeter Array and the Square Kilometer Array operating at cm and dm wavelengths. A small Canadian satellite to study microvariability and oscillations of stars (MOST) is also in the works, with a possible launch date in 2001. Balancing various demands and aspirations is a challenging task in an environment where future funding for research is uncertain. Fortunately, economic conditions are good at present and there seems to be a political awareness that Canada's future in science and technology requires greater government support.

Canals (Martian)

Elusive linear features on Mars claimed to exist by some observers from the late nineteenth century until well into the twentieth. Although isolated streaks had been reported by earlier observers, it was Giovanni Schiaparelli who first gave linear markings prominence on a map of Mars he drew in 1877. He gave them the Italian name *canali*, which can mean 'channels' or 'canals', but was translated as the latter in English reports. The connotation of artificial construction thus became attached to them, though this was not what Schiaparelli had intended—indeed, he disapproved of the term. In the 1880s the canals remained a controversial topic, several respected astronomers claiming to have observed them, but others—notably Asaph Hall—failing to see them.

From the time of his first claimed sightings of canals in 1894, Percival Lowell began to frame the classic scenario of the canals as artificial waterways built by Martians in a last-ditch attempt to irrigate a planet whose water resources were dwindling. This idea, propounded by Lowell in books such as *Mars and Its Canals*, and depicted by him in maps of Mars showing an extensive and intricate canal network, fired the public imagination and infused literature, inspiring such stories as H G Wells's *War of the Worlds*. The power of the popular vision persisted, surviving Eugène Antoniadi's demonstration that the canals were illusory—a result of the observer struggling to resolve elusive detail. When the brain thinks it knows what the eye should see, the eye sees it. Images returned by spacecraft from the late 1960s showed no canals.

Cancer

(the Crab; abbrev. Cnc, genitive Cancri; area 506 sq. deg.) A northern zodiacal constellation which lies between Gemini and Leo, and culminates at midnight in late January. It represents the crab that, in Greek mythology, Hercules crushed underfoot during his fight with the multi-headed Hydra. The name of α Cancri, its brightest star, is Acubens, which comes from the Arabic word meaning 'the claw'. The brightest stars of Cancer were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

An inconspicuous constellation, the brightest stars in Cancer are β Cancri, magnitude 3.5, δ Cancri (Asellus Australis), magnitude 3.9, and ι Cancri, a wide double star with yellow (G8) and bluish-white (A3) components, magnitudes 4.0 and 6.6, separation 30″. Another interesting star is ζ Cancri (Tegmine), a quadruple system consisting of two yellow (F8 and G5) components, magnitudes 5.4 and 6.0, separation 0.6″, period 59.7 years, with a third component, also yellow (F9), magnitude 6.2, separation 6.2″, which revolves around the others in about 1150 years, and a fourth, unseen component which is thought to revolve around the third in about 17.6 years. The constellation also contains the Mira-type variable star R Cancri (range 6.1–11.8, period about 362 days).

Midway between and slightly to the west of γ and δ Cancri is Praesepe (the Beehive or Manger; M44, NGC 2632), one of the most magnificent open star clusters in the sky, which, at a distance of about 160 pc, is just visible to the unadied eye as a faint misty patch. Another interesting open cluster is M67 (NGC 2682), which contains about 200 stars between eighth and fourteenth magnitude.

Candy, Michael Philip (1928–94)

Celestial mechanician, born in Bath, England. While at the Royal Greenwich Observatory became the first astronomer both to discover a comet and to calculate its orbit (Comet Candy 1960), became director of the Perth Observatory, which he supervised into measurements of minor planets and comets, including a vast number of positions for Halley's Comet in 1986.

Canes Venatici

(the Hunting Dogs; abbrev. CVn, gen. Canum Venaticorum; area 465 sq. deg.) A northern constellation which lies between Ursa Major and Boötes, and culminates at midnight in early April. It was named by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* though the celestial figure had been shown in earlier charts dating back to 1533. Previously its stars had been included in Ursa Major.

A rather inconspicuous constellation, the brightest star in Canes Venatici is α Canum Venaticorum (Cor Caroli), a wide binary with bluish-white (A0) and white (F0) components, magnitudes, 2.9 and 5.6, separation 19.4″, the former of which is the prototype of a class of magnetic spectrum variable stars. There are no other stars brighter than fourth magnitude. Another interesting variable is the Mira-type star R Canum Venaticorum (range 6.5–12.9, period about 329 days).

Towards the boundary of Canes Venatici, rather more than halfway between α Canum Venaticorum and α Boötis (Arcturus), lies M3 (NGC 5272), a sixth-magnitude globular cluster. Also towards the boundary of Canes Venatici, but this time about 4° south-east of the star η Ursa Majoris (the last of the bright stars in the tail of the Great Bear) lies the eighth-magnitude Whirlpool Galaxy (M51, NGC 5194), so-called because of its noticeable spiral structure, first observed by Lord Rosse with his 1.8 m (72 in.) reflector in 1845. Three other bright galaxies in Canes Venatici are M94 (NGC 4736—eighth magnitude), M106 (NGC 4258—eighth magnitude) and M63 (NGC 5055—ninth magnitude).

Canis Major

(the Greater Dog; abbrev. CMa, gen. Canis Majoris; area 380 sq. deg.) A southern constellation which lies between Lepus and Puppis, and culminates at midnight in early January. It represents one of the two dogs of Orion (the Hunter), which dominates the sky to the north-west (the other dog being represented by Canis Minor). Its brightest star, α Canis Majoris (Sirius), is known as the 'dog star'. The brightest stars of Canis Major were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A small constellation, Canis Major is easily found by virtue of Sirius, which at magnitude -1.4 is the brightest star in the sky and lies on a continuation of a downward line joining the stars δ, ε and ζ Orionis, in Orion's belt. Sirius is also the brighter component of a close binary, its companion (Sirius B) being a white dwarf, magnitude 8.4, separation 4.6″, period 50 years. Other bright stars include ε Canis Majoris (Adhara), a double star with bluish-white (B2) and yellow components, magnitudes 1.5 and 7.9, separation 7.5″, δ Canis Majoris (Wezen), magnitude 1.8, and β Canis Majoris (Mirzam), magnitude 2.0. There are eight other stars of magnitude 4.0 or brighter.

Other interesting objects in Canis Major include the Algol-type variable star R Canis Majoris (range 5.7–6.3, period 1.14 days), the eclipsing binary UW Canis Majoris (range 4.8–5.3, period 4.39 days) and two open clusters, M41 (NGC 2287), which consists of about 100 stars fainter than seventh magnitude and is just visible to the unaided eye about 4° south of Sirius, and NGC 2362, which consists of about 40 stars fainter than magnitude 7.5 surrounding τ Canis Majoris (magnitude 4.4).

Canis Minor

(the Lesser Dog; abbrev. CMi, gen. Canis Minoris; area 183 sq. deg.) A northern constellation which lies between Gemini and Monoceros, and culminates at midnight in mid-January. It represents one of the two dogs of Orion (the Hunter), which dominates the sky to the west (the other dog being represented by Canis Major). Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small constellation, the brightest stars in Canis Minor are α Canis Minoris (Procyon), which at magnitude 0.4 is the eighth brightest star in the sky, and β Canis Minoris (Gomeisa), magnitude 2.9. There are no other stars brighter than fourth magnitude. Procyon, like α Canis Majoris (Sirius) to the south-west, has a white dwarf companion (Procyon B), magnitude 11.3, separation 5″, period 41 years. There are no bright star clusters, nebulae or galaxies in Canis Minor.

Cannon, Annie Jump (1863–1941)

Astronomer, born in Dover, DE. Taught astronomy by her mother and at Wellesley. In 1896, she joined 'Pickering's Women,' at Harvard College Observatory to reduce data and carry out astronomical calculations. E C PICKERING had conceived a long-term project to obtain and classify stellar spectra. Begun in 1886 by Nettie Farrar and WILLIAMINA FLEMING, the first stage was to examine the spectra of more than 10 000 stars and develop a classification system containing 22 classes, modified by Antonia Maury. Annie Cannon used her own examination of bright southern hemisphere stars to divide them into spectral classes O, B, A, F, G, K, M and so on, and reclassified the previously classified stars. The resultant *Henry Draper Catalog* listed the spectral classes of nearly 400 000 stars. Cannon also published catalogs of variable stars (including 300 she herself discovered).

Canopus

The star α Carinae, named for the chief pilot of the fleet of Menelaos, who died in Egypt *c*. 1193 BC on the return from the Trojan War, the star being prominent at the time. It is the second brightest star, having an apparent magnitude of -0.62. It is a cream giant, spectral type F0Ib, at a distance of 326 light-years; its parallax is $0.010''$, and it has an absolute magnitude of -5.6.

Cape York Meteorite

An iron meteorite that fell at Cape York in northern Greenland. Its fragments total 58 tonnes, making it the second largest meteorite known. The largest fragment (30.9 tonnes), known to the local people as Ahnighito, had been used by them as a source of iron before the explorer Robert Peary visited the region. He shipped Ahnighito, together with two other fragments—'the Woman' (3 tonnes) and 'the Dog' (400 kg)—to New York. Ahnighito, currently kept at the Hayden Planetarium, is the world's largest meteorite on public display. Two other fragments known by their native names (Savik 1, 3.4 tonnes, and Agpalilik, 20 tonnes) were removed to Denmark in the twentieth century.

Capella

Capella—the 'Goat Star' in the constellation Auriga, the 'Charioteer'—is the sixth brightest star in the sky, third in the Northern hemisphere. It is a well-known spectroscopic binary of yellow giants, appears to form a physical system with Capella HL, an outlying pair of RED DWARFS, and is a member of the extended Hyades MOVING GROUP (coeval with the nuclear region of the nearby young cluster). The giants of Capella are nearly twins, but differ just enough in mass to fall in distinctly separate evolutionary phases: the secondary is a lithium-rich fast-rotating Hertzsprung gap star, while the more advanced primary is a lithium-depleted, slowly rotating 'clump' giant. Capella is a linchpin of the stellar mass scale, and long has been a testbed for interferometric techniques and evolutionary models. Capella displays substantial x-ray and far-ultraviolet emissions—perhaps an exaggerated form of solar magnetic activity—making it a popular target for a long succession of space observatories. The origin of the prominent high-energy phenomena of the system and the curious differences between the two very well-characterized G-type giants continue to provoke lively debate in the stellar community.

Background

Capella (α Aurigae; HD 34029; BS 1708; Gl 194) is a nearby ($d = 12.9$ pc) bright ($V = 0.08$) multiple-star system consisting of a pair of nearly identical yellow giants (G8 III (Aa) + G1 III (Ab)) in a tight 0.7 AU, 104 day low-eccentricity orbit, circled at a great distance ($\sim 10^4$ AU) by a looser 50 AU, $\sim$ 300 yr binary of red dwarf stars (Capella HL; Gl 195; dM2 (H), dM5 (L)). The system shares the space motion of the Hyades open cluster, and O J Eggen has deemed it a member of the Hyades Moving Group (or 'Supercluster'). The spectroscopically determined masses ($2.6 M_\odot$ for the primary, $2.5 M_\odot$ for the secondary) indicate an evolutionary age of 600 million yr, similar to the cluster turn-off time of the Hyades nucleus. Figure 1 depicts the spatial arrangement of the system.

The main pair of yellow giants form a SPECTROSCOPIC BINARY STAR with radial velocity amplitudes of 26 km s^{-1} and 27 km s^{-1} (for Aa and Ab, respectively), on top of a recessional velocity of 29 km s^{-1}. The 0.″056 separation of the two giants has been cleanly resolved by a variety of interferometric techniques, beginning with Anderson's pioneering work at Mt Wilson in 1919, and extending more recently to the first true spatial maps in 1995 by the Cambridge Optical Aperture Synthesis Telescope (COAST). Spectroscopic monitoring of the radial velocity swings of the companions, accurate UV–optical–IR photometry, interferometric measurements of the orbital dimensions, narrow-band speckle reconstructions of the relative brightnesses and a highly precise PARALLAX from Hipparcos allow refinement of the stellar parameters to a degree rarely matched in binary-star astronomy. The physical dimensions of the Capella giants, and their orbit, are contrasted in figure 2 with the Sun, the solar system and the nearby dwarf-star binary α Centauri (G2 V + K1 V). α Cen shares superficial similarities with Capella, in that it is a multiple system consisting of a relatively tightly bound double (the G and K dwarfs) with a distant lighter companion (in this case the dM star Proxima Centauri). α Cen is, however, only one-third the total mass of the Capella system.

The puzzling visual spectrum

The visual spectrum of Capella was recorded by numerous observers at the close of the 19th century. W W Campbell, and independently H F Newall, discovered the periodic Doppler shifts (see DOPPLER EFFECT) that pointed to the binary nature of the star. The overall spectrum was puzzling, however: the absorption lines of one component were sharp and distinct, but those of the other were barely recognizable. At the same time, interferometric work in the 1920s indicated that the two stars were comparable in brightness. In the 1950s, O Struve and S M Kung, and later K O Wright, succeeded in measuring the secondary spectrum. Wright—who applied a cleverly designed mechanical subtraction technique to isolate the secondary spectrum from the composite—described the secondary's as 'diffuse', leading to a 'veiling' (or dilution) of the primary spectrum. The washed-out appearance of the secondary spectrum was attributed, at the time, to enhanced atmospheric turbulence or fast rotation.

In the 1960s, G Wallerstein called attention to the lithium absorption spectrum—a signature of evolutionary 'youth', completely dominated by the secondary star—and demonstrated that the fast-rotation hypothesis was correct. In the early 1970s, AM Boesgaard detected a weak Li I absorption in the primary, leading to the evolutionary scenario devised by I Iben (illustrated in the lower right portion of figure 2). Both of the Capella stars began their lives on the upper main sequence (MS) as late-B dwarfs. The slightly more massive primary evolved away from the MS first, as a hydrogen shell source, ascended the giant branch, ignited its helium core and then returned to the base of the red giant branch as a core helium burning star, losing its lithium by deep convective mixing along the way. The helium burning phase is relatively long lived, perhaps 20% of the MS lifetime; thus evolved stars tend to collect in that part of color–magnitude diagrams, leading to a 'clump.' Meanwhile, the slightly less massive secondary has only recently evolved away from the MS, at present is in the hydrogen shell burning 'first-crossing' phase, and the lithium dilution episode lies in its future. Because the horizontal portion of the shell-burning trajectory is traversed very rapidly, in perhaps only 0.1% of the MS lifetime, few stars are found there in color–magnitude diagrams, and the region has come to be called the 'Hertzsprung gap'. Thus while the Capella giants fall close to one another in the Hertzsprung–Russell diagram (i.e. in surface temperature and luminosity), the primary has covered considerably more evolutionary 'distance' than the secondary to arrive at its present position; subsidiary

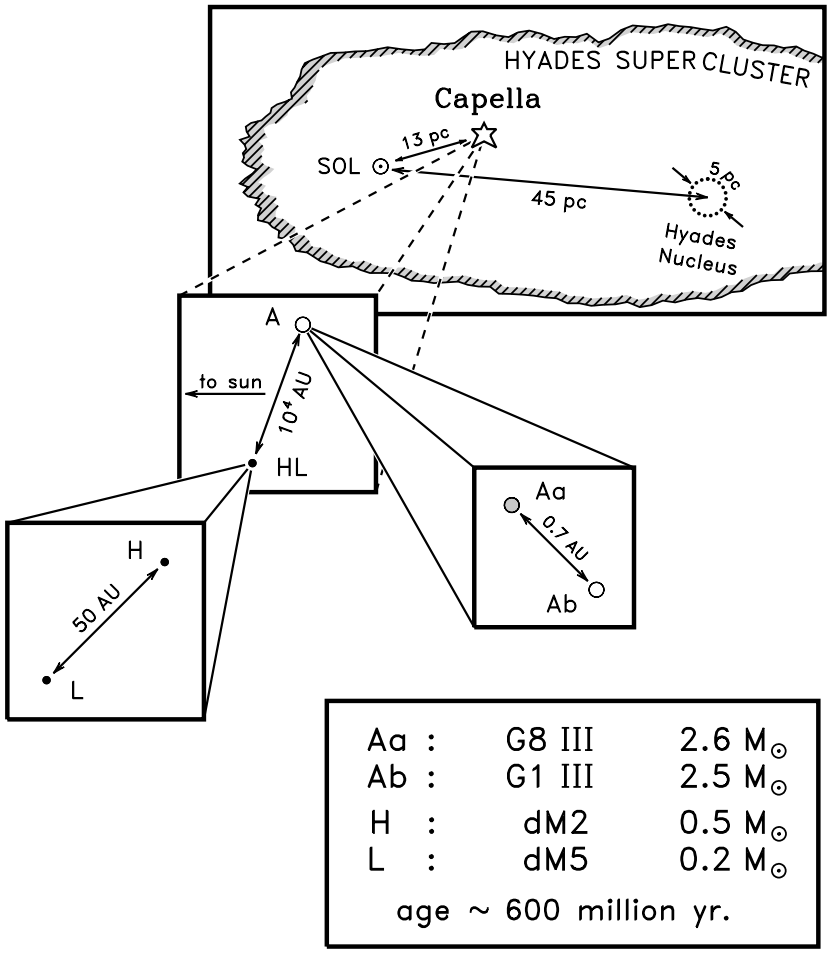

Figure 1. Cartoon of Capella: its constituent stars and relationship to the coeval Hyades cluster and the Sun. (The Sun is much older than the Hyades, and only coincidentally finds itself moving through the outskirts of the cluster.)

properties such as rotation, lithium abundance and CNO isotopic ratios tell the tale.

In the 1980s, F C Fekel and collaborators obtained high-precision rotational velocities for both components: $v_{\rm Aa} \sin i = 6$ km s^{-1}; $v_{\rm Ab} \sin i = 36$ km s^{-1}. From that time to the present, there has been steady refinement of the orbital dimensions of the Capella system using interferometry, and further improvements in the spectroscopic orbit. Very recently, the new Hipparcos parallax for Capella yields a distance (12.9 pc) about 3% closer than the previous trigonometric estimates, implying luminosities about 6% less. The radius of the primary is $13R_\odot$; that of the secondary is $9R_\odot$. The effective temperatures are 4940 K and 5700 K, respectively.

Figure 3 illustrates (simulated) visible and ultraviolet spectra of Capella at orbital phase $\phi = 0.25$ (the quadrature when Aa is receding at its maximum velocity and Ab is approaching at its maximum), and half a cycle later at $\phi = 0.75$ (Aa approaching; Ab receding). The visible spectrum of each component (middle curve, top panels) was obtained by rotationally smoothing a solar trace by the appropriate $v \sin i$; the absorption feature near 6339 Å is an unresolved close blend. The vertical dotted line marks the rest position of the center sharp absorption. For clarity, the primary spectrum was assumed to be 10% brighter than the secondary at this red wavelength (corresponding to $\Delta V \sim 0.1$ mag); the secondary spectrum is shaded. Note the washed-out appearance of the latter. When the two spectra are combined to yield the composite at the top of each panel, the sharp lines of the primary are diluted in relative flux by a factor of ∼2 and fall on the undulating background provided by the rotationally smeared secondary. No wonder it was so difficult to isolate the secondary contribution in historical noisy photographic spectra.

High-energy measurements

Capella was the first 'normal' extra-solar star detected in x-rays (serendipitously during a sounding rocket flight), and is a bright far-ultraviolet emission-line source. The high 'activity' of the system has made it a popular target for spacecraft observatories, beginning with Copernicus

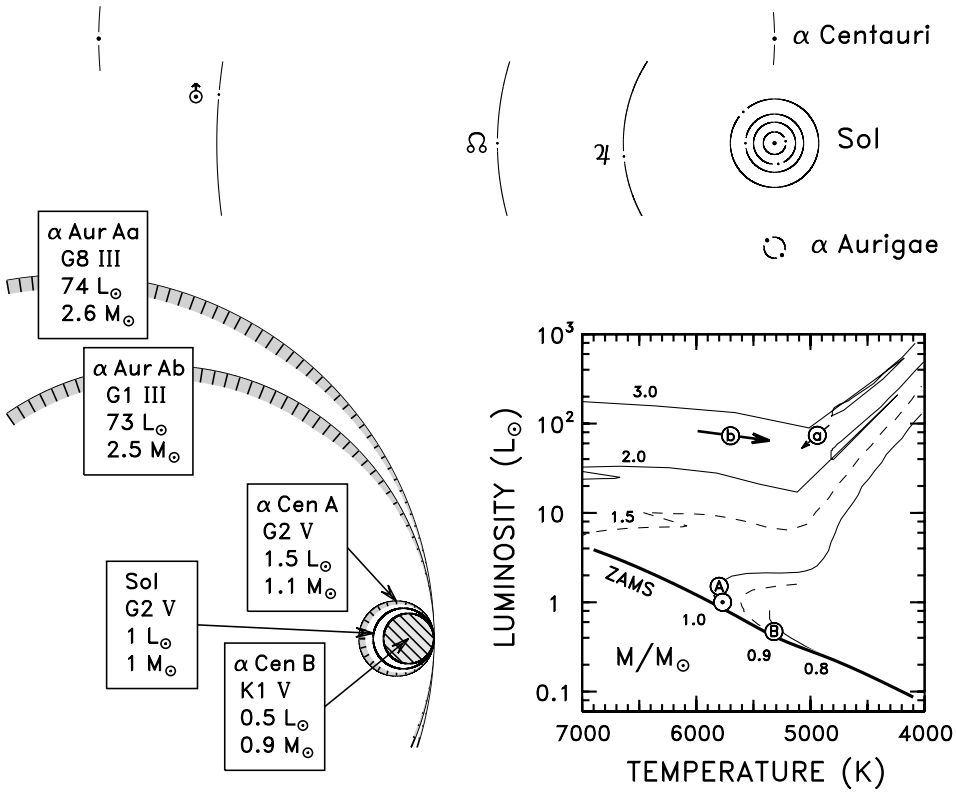

Figure 2. Dimensions of the Capella stars and their orbit, and evolutionary status. (Note: points representing the stars and planets in upper portion of the diagram are not to scale.)

in the mid-1970s, and extending in the modern era to the Japanese x-ray spectroscopy satellite ASCA and the Italian–Dutch high-energy observatory BeppoSAX.

In the early Copernicus work, A K Dupree found strongly *blueshifted* high-excitation O VI λ1032 in Capella, relative to the expected velocity of the primary star at the particular orbital phase observed. She interpreted the shifts as evidence for a massive $T \sim 10^5$ K wind emanating from the primary star. Later with the all-sky survey by HEAO-1, Capella was found to share high x-ray levels with the short-period ($P \sim$ few day) tidally locked RS Canum Venaticorum binaries, and was designated a long-period member of the class. Subsequent studies by T R Ayres and J L Linsky with the far-ultraviolet echelle spectrometer on the International Ultraviolet Explorer, beginning shortly after its launch in 1978, discovered unexpectedly that the fast-rotating G1 III secondary star was responsible for virtually all of the high-excitation emissions of the system (from species such as Si IV λ1393 and C IV λ1548, forming at $T \sim 6 \times 10^4$–10^5 K, conditions characteristic in the Sun of the subcoronal TRANSITION REGION). Only a small contribution was detected from the slowly rotating G8 III primary. (In hindsight, the earlier Copernicus result for O VI could be reinterpreted as slightly *redshifted* emission from the *secondary* star at the particular orbital phase.)

The bottom panels of figure 3 illustrate the effect for the C IV doublet based on line widths, relative shifts and continuum intensities measured in Hubble Space Telescope spectra (GHRS instrument) by B E Wood and collaborators. The vertical dotted line marks the rest position of C IV λ1548. Contrary to the visible region, the G1 secondary star completely dominates the far-ultraviolet line and (weak) continuum emission, while the G8 primary is only a small perturbation. Note also the enormous widths (∼150 km s^{-1} full width at half-intensity) of the C IV components in the secondary star (considering that the velocity scale in this depiction is 'compressed' by a factor of 4 in the lower panels compared with the visible spectra owing to the shorter wavelength but same 10 Å interval). More difficult to see in this rendition are the systematic redshifts of the C IV lines (in both stars) relative to the velocities expected at each orbital phase. Such shifts are recorded commonly in ultraviolet spectra of the Sun, in lines arising from the 10^5 K transition zone, and are thought to be caused by mass motions of material in a complex circulation system within coronal magnetic loops (see CORONAL LOOPS).

In the early 1980s, fast rotation was viewed as the key link between the coronal hyperactivity of the short-period RS CVns and long-period Capella. (Tidal synchronization in the semi-detached RS CVn binaries causes each of the component stars to rotate at the orbital period, and thus

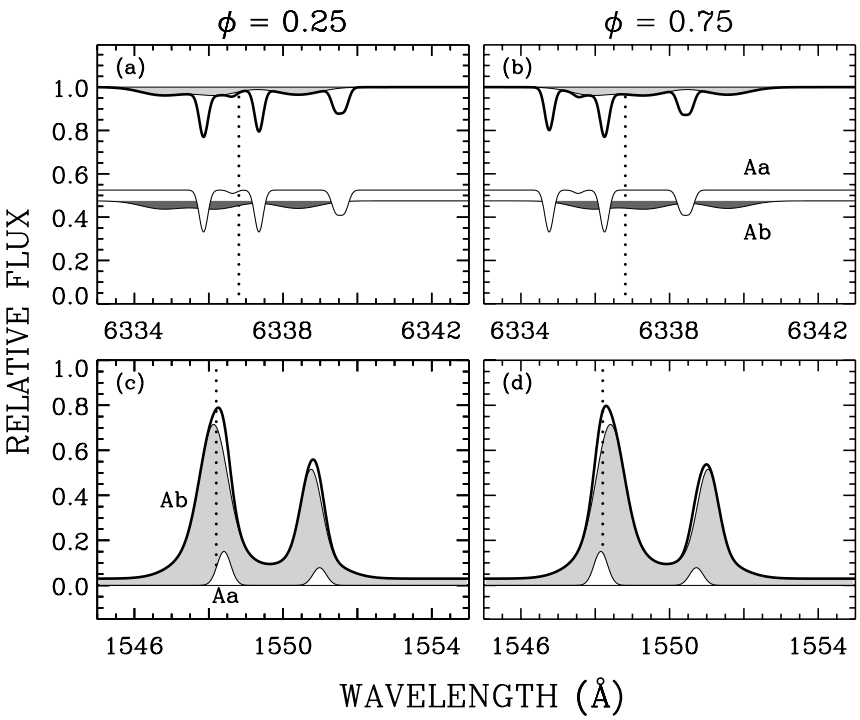

Figure 3. Simulated spectra in visible (top panels) and far-ultraviolet (bottom panels) at opposite orbital quadratures (maximum radial velocity separation).

rapidly since $P_{\rm orb}$ is short.) In reality, Capella is 'half an RS CVn', because just one of the stars rotates rapidly. The connection between fast spin and enhanced coronal activity arguably is through strong surface magnetic fields, produced in the stellar convective envelope by rotation-catalyzed 'dynamo' action.

The dichotomy between the rotation rates of the two nearly identical coeval giants was attributed to the large evolutionary separation that can develop from even a small mass difference (as described previously in Iben's scenario). Indeed, there is an apparent sharp decrease in the spins of stars just past G1 III. The cause of the rapid braking episode currently is a subject of debate (leading contenders are evolutionary redistribution of angular momentum in the stellar interior, and shedding of angular momentum by a strong stellar wind), but there is little doubt that many of the curious ultraviolet (and visual) properties of Capella can be understood if the G8 star already has passed through the rapid braking stage, while the G1 star is poised at the brink.

Current research

Recent investigations have focused on high-spectral resolution ultraviolet measurements of Capella at critical orbital phases, particularly dynamical processes revealed in global redshifts of the high-temperature lines, and the mysterious 'broad components' (extended high-velocity wings on the emission line profiles) identified by B E Wood which might be signatures of the stellar analogs of solar 'transition zone explosive events'. Another area of interest is the recognition that despite its strong far-UV emissions, the G1 secondary star (and other fast-rotating Hertzsprung gap giants) is relatively deficient in its coronal x-ray luminosity. In fact, the G1 star probably has about the same x-ray brightness as the G8 primary, despite a 10-fold advantage at C IV λ1548. The paradox is seen clearly in UV measurements by HST of the coronal forbidden line Fe XXI λ1354, which is detected in both of the giants at about equal strengths. The primary star, itself, falls in a distinct class of active clump giants, the prototype of which is β Ceti (K0 III) and which includes two of the four Hyades red giants (evolutionary cousins of the Capella stars). Another curiosity of Capella is that, despite the substantial coronal emissions (of both components), and intense scrutiny by historical and contemporary x-ray and ultraviolet missions, there are surprisingly few reports of variability and a remarkable absence of FLARES. In contrast, dramatic x-ray variability and flare activity (including nonthermal emission at radio frequencies) are trademarks of the classical RS CVn binaries.

Summary

As a nearby bright spectroscopic binary of yellow giants—one of them a rare Hertzsprung gap star—and trailing emissary of the young Hyades open cluster, Capella has drawn the attention of spectroscopists for more than a century. Astronomers have tested interferometric techniques on the 'subvisual' orbit for nearly as long.

About 30 yr ago, the nature of the somewhat mysterious secondary star was unraveled, and explained in the context of a compelling evolutionary scenario. With the development of space observatories in the mid-1970s, Capella again found itself in the astronomical spotlight, often a prominent entry in the commissioning target list of a new mission. Interest in the system—and its message concerning the role of stellar structure on the evolution of coronal magnetic activity—remains unabated today.

Capricornus

(the Sea Goat; abbrev. Cap, gen. Capricorni; area 414 sq. deg.) A southern zodiacal constellation which lies between Sagittarius and Aquarius, and culminates at midnight in early August. The origin of the unusual constellation figure, which comprises the head and forelimbs of a goat and tail of a fish, dates back to Babylonian times and has also been associated in Greek mythology with Pan, who had the horns, legs and ears of a goat and turned the lower half of his body into that of a fish as he plunged into the Nile to escape the monster Typhon. The brightest stars of Capricornus were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A rather inconspicuous constellation, the brightest stars in Capricornus are δ Capricorni, (Deneb Algedi), magnitude 2.9, and β Capricorni (Dabih), a multiple system consisting of two main components, a yellow (F8, combined) primary, magnitude 3.1, which is a spectroscopic triple star, and a bluish-white (B9) secondary, magnitude 6.1, which has a magnitude 10.2 companion, separation 0.85″. There are three other stars brighter than fourth magnitude, including α^2 Capricorni (Secunda Algedi or Secunda Giedi), yellow (G8), magnitude 3.6, a naked-eye double with unrelated α^1 (Prima Algedi or Prima Giedi), yellow (G3), magnitude 4.3, separation 378″, both stars having fainter companions. Another interesting object is M30 (NGC 7099), an eighth-magnitude globular cluster.

Carbon Stars

The intrinsic properties of carbon stars

In 1868 ANGELO SECCHI , S.J., announced that he had found a fourth type of stellar spectrum. His first three types, designated by Roman numerals of course, were stars with hydrogen lines (now A and B stars), stars with metallic lines (now types F, G and K) and stars with absorption bands that diminished toward longer wavelengths (now types M and S). Secchi's type IV showed bands tailing toward shorter wavelengths. By inserting a carbon arc in his visual spectroscope he immediately recognized that the new bands were due to C_2 and other C compounds, now known to be largely CN. The difference between the oxide bands of Secchi's type III and the C bands of type IV was recognized by Fujita to be controlled by the chemistry of the very stable molecule CO. If the abundance of O exceeds that of C the remaining O, after forming CO, is available to form the oxide molecules seen in spectra of types M and S. However, in stars with C > O the O is used up in CO and the remaining C is available to form carbon molecules such as C_2, CN and CH.

The modern system of classification of carbon stars was established by Keenan (1993), who subdivided them into three sequences C-R, C-N and C-H corresponding to the old RN and CH star classifications. A numeral follows to indicate the temperature sequence, e.g. from C-N1 to C-N9. Keenan's full description of the spectra includes the strengths of the C_2, CN and Merrill–Sanford bands as well as the $^{12}C/^{13}C$ ratio and the Li line strength. An index of the s-process enhancement would be useful, but is difficult to observe except at high spectral resolutions.

The intrinsic luminosities of carbon stars can be derived either from HIPPARCOS PARALLAXES or by association of the carbon star with a stellar system whose distance has been determined. In addition, photometry from the visual to the K band (2.2 μm) is necessary. By limiting the sample to stars with parallaxes at least three times their probable error and errors less than 1.5 marcsec a list of 33 objects was assembled by Wallerstein and Knapp (1998). Most of the stars are of type C-N with only a few C-H, C-R and Mira stars represented. If the criteria for acceptance into the sample are lowered one runs into a statistical quagmire and the apparent spread in M_V and M_K increases rapidly.

There are many carbon stars in other galaxies such as the MAGELLANIC CLOUDS, where extensive surveys have been conducted. Since the distances to the clouds are now fairly well known, the luminosities of the carbon stars may be calculated. M_K values as bright as -9 are present, while the Hipparcos sample of stars mentioned above included only four stars brighter than $M_K = -8$ and none brighter than $M_K = -8.8$. The C-R stars show $M_K \simeq -5$ and $M_V \simeq +1.0$, significantly fainter than the C-N stars.

The calculation of effective temperature, $T_{\rm eff}$, depends only on measuring the star's total radiative flux and angular diameter. The latter can be done either by lunar occultation or by interferometry. As of 1998, 26 C-N stars have had their $T_{\rm eff}$ values estimated in this way. The range of values lies from 2000 to about 3300 K. The C-R and C-H stars are considerably warmer with $T_{\rm eff}$ values from 4000–5000 K, as determined by analysis of their spectral lines.

Carbon star masses are known only by indirect inference. Stellar models that lead to atmospheric carbonization by helium shell flashes and mixing can be followed for stars of roughly 1–3$M_\odot$. The upper limit may be as large as 5 or 6$M_\odot$ but the mass-function for main sequence stars ensures that such objects should be relatively rare. The spectroscopic orbits of C-H stars indicate masses near 0.8$M_\odot$ but the C-H primaries appear to have obtained their carbon-rich atmospheres by transfer from their current white dwarf companions, whose original masses are unknown, but probably were limited to the numbers suggested above. The C-H stars in the Large Magellanic Cloud, however, are very luminous and their origins are uncertain.

The evolution of carbon stars has intrigued stellar astronomers for some 50 years; i.e., ever since the significance of the $3\,^4\mathrm{He} \rightarrow {}^{12}\mathrm{C}$ reaction was pointed out independently by Öpik and Salpeter respectively in 1951 and 1952. Temperatures above about 10^8 K are needed for the triple-alpha reaction to take place, while the excess carbon eventually appears in the stellar atmosphere where the temperature ranges from 2–5 $\times$ 10^3 K. In addition, detailed abundance ratios such as the $^{12}C/^{13}C$ ratio and the enhancement of many heavy elements must be accounted for. In stars of less than about 2.0$M_\odot$ the triple-alpha reaction ignites at the tip of the red giant branch in a 'core-flash' (because its rate increases exponentially at first) but the resulting helium produced by the flash and subsequent quiescent burning seem to be confined to the stellar core. In more massive stars He burns quiescently, building up a C core with some extension to ^{16}O as ^{12}C captures an additional ^4He nucleus. Eventually, low mass stars with C cores and helium envelopes can ignite their He at the C–He boundary in a 'shell-flash'. By a series of events involving sudden convective mixing the ^{12}C reacts with protons to produce ^{13}C which, in turn, can react with helium nuclei to produce oxygen and free neutrons. The capture of the free neutrons by iron and other heavy elements then produces many of the heavy elements from rubidium to lead with specially conspicuous elements such as Sr, Y, Zr, Ba and the light rare earths. Even the unstable element Tc, with a half-life of 2 $\times$ 10^5 yr, is produced and convected to the stellar surface, where it is observed in some carbon stars and many S-type stars.

How much of this is observed on the surfaces of carbon stars? The observation of carbon stars with high spectral resolution from 400 to 2400 nm is not difficult. However, the analysis of the observed spectra is extremely complicated and uncertain due to the huge number of atomic lines and molecular bands in the spectra of carbon stars. While complete analyses are difficult, restricted analyses can be successfully carried out. For example, the ratio of $^{12}C/^{13}C$ can be determined accurately and ranges from about 100 to near 4 in carbon stars, thus showing the heterogeneity of evolutionary histories. Most of the C-N

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stars show $^{12}C/^{13}C$ ratios above 30 while only a few show ratios near 4. The C/O ratios range from 1.01 to 1.76 with a mean of 1.15 ± 0.03. Nitrogen is almost never enhanced even in stars with low $^{12}C/^{13}C$, which is surprising. In fact, the sum of C+N+O is rarely enhanced in C-N stars despite the necessity of an enhancement of carbon for the star to be a carbon star.

The C-R stars are easier to analyse because of their higher $T_{\rm eff}$ values, from 4200 to 5000 K, but they are rare and few are bright. They all show enhanced ^{13}C with the $^{12}C/^{13}C$ ratio ranging from 4 to 9. Nitrogen is also enhanced, showing systematic CNO cycling after ^{12}C enhancement. None of them show heavy element enhancments. Two Cepheids with early R-type spectra have been analysed and show similar properties to the nonvariable R stars.

The C-H stars are the easiest to analyse because they are relatively hot and substantially metal-poor, so the degree of blending is greatly reduced. As mentioned above, they seem to have inherited their atmospheres from their now defunct companions. Their $^{12}C/^{13}C$ ratios are either less than 8 or more than 25. Some of the latter group may be 100 or more. All of them are metal-poor by factors of 3–50. Carbon and nitrogen are enhanced by about a factor of 10, oxygen is normal, and hence C+N+O turns out to be enhanced by a factor of 2–5. Apparently their low initial abundances of everything from C to Fe have made their nucleosynthesis processes more evident. The greatest enhancements are shown by s-process elements, i.e., Sr, Y, Zr, Ba and rare earths. The neutron source is probably the $^{13}C(\alpha, n)^{16}O$ reaction.

Circumstellar envelopes

In addition to being of intrinsic interest from the STELLAR EVOLUTION viewpoint carbon stars are important for the evolution of the interstellar medium and hence the Galaxy as a whole. Near-infrared observations out to 2.2 μm of RED GIANTS were first made in the 1960s and soon revealed many stars whose radiation beyond about 1.0 μm greatly exceeds what was expected from model atmospheres. It was soon recognized that the infrared excess had to be due to relatively cool gas and dust while its intensity could only be understood if the circumstellar matter filled a volume that was much larger than that of the star itself. Earlier observations of some red giants and supergiants had shown spectral lines of Na I and Ca II with Doppler shifts corresponding to material departing from the stellar surface at up to 20 km s^{-1}. Over the subsequent decades observations of circumstellar envelopes were extended to the middle infrared (5–30 μm), far infrared (30–200 μm), submillimeter (0.2–1.0 mm), millimeter (1–10 mm) and radio (10 mm and longer) spectral regions. Many instruments have contributed to our knowledge of circumstellar envelopes but the IRAS survey and very recently the ISO satellite have been responsible for major advances.

Circumstellar dust radiates in the near and mid-infrared wavelengths. The dust absorbs the starlight and is heated to temperatures in the range 1000–100 K near the star, diminishing at larger distances. The infrared spectra of M and C stars differ because of the different properties of silicate and carbon-compound dust. Carbon dust is opaque at visual wavelengths, hence greatly reducing the visible flux, while silicates are partially transparent (soot is black, while glass is transparent). The gas comes into thermal equilibrium with the dust by collisions, thus heating the gas. This provides sufficient excitation for many molecules to radiate at wavelengths corresponding to rotational transitions. The most common radiating molecule is CO, of course, where the (1–0), (2–1), (3–2) etc. transitions are often detected.

The envelopes around carbon stars provide a laboratory for organic, and even some inorganic, chemistry that cannot be realized on the earth. Near the star the high density together with temperatures as high as 1500 K ensure equilibrium chemistry but in the outer layers the reaction rates must be carefully considered. The star IRC+10216 seems to show the richest chemistry with a vast number of organic compounds present and even some chlorides and fluorides showing up in the inner envelope. Further out photochemical reactions become important as the interstellar radiation field with photon energies up to 10 eV penetrates the envelope; some ions are present so ion–molecule chemistry becomes important.

Infrared surveys such as IRAS have revealed that all C-N stars have infrared excesses indicating mass loss. The C-R and C-H stars do not show evidence of mass loss. Mass loss rates can be calculated from the equation of continuity: $\dot{M} = 4\pi r^2 \rho(r) V_\infty$, where the density, ρ, at the distance r must be estimated from a model and V_∞, the velocity of the moving envelope, can be estimated from the width or separation of emission lines of CO in the mm and submm regions. Mass loss can be detected readily down to $10^{-7} M_\odot$ yr^{-1} and in a few cases to almost 10^{-8}. At the other end of the scale mass loss rates as large as 10^{-5} or even a few times $10^{-5} M_\odot$ yr^{-1} have been calculated. Carbon stars with such high mass loss rates are virtually invisible in the visual region but are particularly important because of their rapid evolution and their contribution of a vast array of molecules to the interstellar medium.

Mass loss by carbon and other asymptotic giant branch stars presumably ceases when the outer hydrogen envelope has been completely ejected. The remaining core of the star then shrinks and its effective temperature rises. The last phases of mass loss may involve a much higher velocity than the usual 10–20 km s^{-1} of the gentle wind from the carbon star. This so-called 'superwind' can reach 1–200 km s^{-1} and can sweep up the material that was ejected earlier. A shock will form where the winds interact, causing the shocked gas to be greatly heated. In addition, the evolving star will shrink until its temperature reaches $1–2 \times 10^5$ K. The radiation from such a star will ionize the surrounding gas and the resulting configuration will constitute a PLANETARY NEBULA. Hence the final stages of a mass-losing carbon star may be described as 'Death and Transfiguration', the title used by G R Knapp at a

Carbonaceous Chondrite

A meteorite having a higher carbon content than other classes of meteorite. Carbonaceous chondrites account for about 3% of all known chondrites. They are classified according to the proportion and size of the chondrules (millimeter-sized grains) they contain. One very rare subclass lacks chondrules, and so are actually achondrites. They are very similar in composition to the Sun (with the exception of volatiles), and the material from which they are formed is believed to have condensed from the solar nebula very early in the history of the solar system, making them vital pieces of evidence in the study of cosmogony. The carbon content is in the form of organic compounds, including amino acids—important biological precursors. They may therefore hold clues to the origin of life. The Allende meteorite is the largest known example, with an estimated total mass before fragmentation of 2 tonnes.

Cardan [Cardano; Cardanus], Jerome [Geronimo; Hieronymus; Girolamo] (1501–76)

Lawyer, mathematician and physician, born in Pavia, Milan, Italy. Lived a life of family and professional drama worthy of a novel and fully documented in an autobiography. Became professor of mathematics at Padua, and of medicine at Pavia and Bologna. Prolific author (200 works) of which his greatest work was *Ars Magna* (1545, *Great Art*) which gave the first algebraic solution of cubic equations. In 1570 he was imprisoned for a few months by the Inquisition. He was accused of heresy, particularly for the book *De Astorum Iudiciis* in which he cast the horoscope of Christ, attributing events of His life to astrological influences. As a result he was barred from teaching. Correctly predicted through astrology the exact date of his own death but may have cheated by committing suicide (*see* ABU'L-HASAN IBN YUNUS).

Carina

(the Keel; abbrev. Car, gen. Carinae; area 494 sq. deg.) A southern constellation which lies between Vela and Chamaeleon, and culminates at midnight in late January. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, from stars that formed part of the ancient constellation of Argo Navis (the Ship), which had been included by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A conspicuous constellation, the brightest stars in Carina are α Carinae (Canopus or Suhel), which at magnitude -0.6 is the second brightest star in the sky, β Carinae (Miaplacidus), magnitude 1.7, ε Carinae (Avior), magnitude 1.9, and ι Carinae (Aspidiske), magnitude 2.2. There are 14 other stars of magnitude 4.0 or brighter. ι and ε Carinae together with δ and κ Velorum make up an asterism called the False Cross, as it is sometimes confused with the constellation Crux (the (Southern) Cross). Variable stars in Carina include η Carinae, an eruptive, high-luminosity star (observed range -0.8 to 7.9) surrounded by a shell of nebulosity (the Homunculus Nebula) expelled in the nineteenth century, and the Mira-type variables R Carinae (range 3.9–10.5, period about 309 days) and S Carinae (range 4.5–9.9, period about 149 days).

The Milky Way cuts across the north-eastern part of Carina and the constellation contains a number of interesting star clusters and nebulae, including NGC 3532, a large ($60' \times 30'$), spectacular open cluster of about 150 stars between eighth and twelfth magnitude, NGC 2808, a sixth-magnitude globular cluster, and NGC 3372 (the Eta Carinae Nebula), a large (>4 sq. deg.), bright emission nebula centred on η Carinae.

Carlsberg Meridian Telescope

A 7 in (17.8 cm) diameter refractor, formerly known as the Carlsberg Automatic Meridian Circle. It is part of the OBSERVATORIO DEL ROQUE DE LOS MUCHACHOS on La Palma and is dedicated to carrying out high-precision optical astrometry.

It is operated jointly by the Copenhagen University Observatory, the Institute of Astronomy, Cambridge and the Real Instituto y Observatorio de la Armada en San Fernando.

When it was first moved to La Palma in 1984, it was one of the first fully automatic telescopes in the world. Since 1997, the telescope has been operated remotely via the Internet from Britain, Denmark or Spain.

Recent upgrades include installation of a CCD which can observe about 70 000 stars a night down to visual magnitude 17. It is being used to map the northern sky between -3° and $+30^\circ$ in declination.

Carnegie Observatories

The Carnegie Observatories were founded in 1902 by George Ellery Hale. Their first facility was the MOUNT WILSON OBSERVATORY, located in the San Gabriel Mountains above Pasadena, California. Originally a solar observatory, it moved into stellar, galactic and extragalactic research with the construction of the 60 in (1.5 m), and 100 in (2.5 m) telescopes, each of which was the largest in the world at the time of its construction. From the 1940s through the 1970s Carnegie, in partnership with the California Institute of Technology, ran the Mount Wilson and PALOMAR OBSERVATORIES.

Today, the offices of the Observatories remain in Pasadena, but their main observational facility is the LAS CAMPANAS OBSERVATORY located in the southern fringes of Chile's Atacama Desert. There, Carnegie operates the 1 m Swope and 2.5 m du Pont Telescopes. The twin 6.5 m Magellan Telescopes, built in partnership with Harvard, MIT, and the Universities of Michigan and Arizona, will be completed in 2002.

Carnegie Observatories have played a central role in the history of twentieth century astronomy. Major contributions of Carnegie astronomers include Shapley's use of globular clusters to establish the structure of the galaxy, Hubble's discovery of the expansion of the universe, Baade's work on stellar populations, and Sandage's pursuit of the Hubble Constant. Today, the staff of about twenty astronomers works on stellar populations, the structure and evolution of galaxies, and cosmology. The Observatories are one of five departments of the Carnegie Institution of Washington, a private, non-profit organization devoted to scientific research.

Carrington, Richard Christopher (1826–75)

English amateur astronomer, first person to observe (1859) a solar flare, 'two patches of intensely bright and white light', confirmed by R Hodgson and by the correlated appearance of auroras, seen as far south as Cuba, and magnetic disturbances, observed at the Kew Observatory. Carrington noted the connections, but cautioned that 'one swallow does not make a summer'. Only about 50 flares have been observed in the white light spectral range, as used by Carrington's visual observations with a 4.5 in refractor.

Carter National Observatory

The Carter National Observatory is situated in the Botanic Gardens in Wellington, New Zealand. Opened in 1941, the observatory is equipped with a 41 cm Boller and Chivens, an historic 23 cm Cooke photo-visual refractor and a 36 seat Zeiss planetarium. The staff are involved in research, school and tertiary education programs.

The observatory currently has eight full time members. Research programs are run in collaboration with a consortium of New Zealand and Japanese universities and involve micro-lensing and the search for dark matter.

Cartwheel Galaxy

A peculiar galaxy in the constellation of Sculptor that derives its name from its wheel-like appearance. The Cartwheel has a ring-shaped 'rim', 150 000 light-years in diameter, that contains billions of recently formed stars and which is dominated by massive clusters of bright blue stars and HII regions. The nucleus, or 'hub' of the galaxy contains a predominantly older population of stars and is surrounded by faint arms, or 'spokes' that stretch out towards the ring. Its striking appearance is the result of a galactic collision. A few hundred million years ago, a smaller galaxy plunged straight through the Cartwheel, which at that time is presumed to have been a normal spiral galaxy. The resulting shock spread out through its gaseous disk like a ripple on a pond, pushing gas and dust before it and compressing it into a ring. The compressed gas clouds collapsed and fragmented, thereby initiating the dramatic burst of star formation that is evident today in the ring. Located at a distance of some 500 million light-years, the Cartwheel is an example of a starburst galaxy (one that is undergoing a major bout of star formation).

Cassegrain Telescope

A type of reflecting telescope based on a design that was produced in 1672 by the Frenchman Guillaume Cassegrain. It utilizes a concave paraboloidal primary mirror and a convex ellipsoidal secondary mirror that is located a short distance inside the focus of the primary. The converging cone of light from the primary is reflected by the secondary, back down the telescope tube and through a hole in the center of the primary to the eyepiece. Because the curved surface of the secondary causes rays of light to converge at a narrower angle than the rays reflected directly from the primary, it increases the effective focal length of the instrument, so enabling an instrument of long effective focal length to be contained within a relatively short tube. Although the focal ratio of a Cassegrain primary mirror is typically in the region of f:3 to f:4, the effect of the secondary mirror enables these instruments to operate at focal ratios in the region of f:10 to f:30.

The standard Cassegrain design produces sharply focused images only in the central parts of its field of view, images away from the center ('off-axis images') being subject to various distortions, or aberrations, such as coma. Good quality images, over fields of view several tens of minutes of arc in diameter, can be obtained with telescopes of the Ritchey–Chrétien design in which the primary is a concave hyperboloid (rather than a paraboloid) and the secondary has a steeper hyperbolic curve than that of a conventional Cassegrain secondary. Another variant on the Cassegrain design is the Dall–Kirkham, which uses a concave ellipsoidal primary and a spherical convex secondary, curves which are easier to make than the paraboloids and hyperboloids of conventional Cassegrains. However, the field of view of a Dall–Kirkham is typically only about one-third of that of a normal Cassegrain.

Most large modern telescopes are based on the Cassegrain design or one of its variants.

Cassegrain, Laurent (*c*. 1629–93)

French teacher and priest, inventor (1672) of the *Cassegrain telescope* configuration, the most widely used reflecting telescope in astronomy. It consists of a concave primary mirror and a convex secondary, in which the compact arrangement of mirrors can be chosen so that aberrations on each mirror cancel each other. Little is known of the life of this shadowy figure, who lived and worked near Chartres and Chaudon.

Cassini, César-François [Cassini de Thury, known as Cassini III] (1714–84)

Second son of JACQUES CASSINI, born in Thury, Oise, France. Director of the Paris Observatory (1771), where he concentrated on geodesy and made the first modern map of France which, for navigational purposes, would accurately place the French ports relative to Paris. To everyone's surprise, France was some 20% smaller than previously believed, and the King commented that France had lost more territory to the astronomers than to its enemies.

Cassini, Gian Domenico [Giovanni Domenico; Jean Dominique; known as Cassini I] (1625–1712)

Italian-born French astronomer, born in Perinaldo, near Naples. Attracted to astrology in his youth, became Professor at Bologna, during which time he conducted hydrological studies for the Pope to mitigate flooding of the River Po. In 1669 Cassini moved to France and set up the Paris Observatory, remaining director for the rest of his career. He pushed continually for the observatory to acquire the latest technology and make improvements, winning substantial funding. His powerful new telescopes were used to make important findings about the solar system. He saw spots on Mars and measured the planet's rotation period. He also measured the rotation of Jupiter and mapped its spots, bands and flattening at the poles. He timed the revolution of Jupiter's satellites, which allowed the Danish astronomer OLE RØMER to compute the speed of light while he was working in Paris. He made the best map of the Moon until the invention of photography. He observed comets and wrote about planetary and satellite orbits. Although the phenomenon had long been known, possibly from classical times, certainly since the Middle Ages, Cassini was the first to record (1683) scientific observations of the zodiacal light. In 1684 he discovered Iapetus, Rhea, Tethys and Dione, four satellites of Saturn in addition to those previously discovered by HUYGENS. In 1675, he discovered that Saturn's rings are split largely into two parts by a narrow gap—known since as the *Cassini division*. Cassini elaborated on the first major theory of atmospheric refraction, founded on the sine law but opposed the theory of universal gravitation, bequeathing the battle against Newtonianism to his son, Jacques, by whom (and by his grandson and great-grandson) he was succeeded as director of the observatory. The Cassini spacecraft, launched 1987 and scheduled to arrive at Saturn in 2004 to begin exploration of the planet and its moons, is named for him.

Cassini, Jacques [known as Cassini II] (1677–1756)

Astronomer, born in Paris (probably at the Observatory itself), son of JEAN-DOMINIQUE CASSINI, whom he at first assisted, then replaced in official functions as Cassini became blind, and then succeeded as director of the Paris Observatory. Measured proper motion of Arcturus. Cassini II fought continually and unsuccessfully to defend the work of his father and to reconcile observations with the Cartesian theory of vortices. In 1740, understanding the uselessness of his opposition to the new ideas he progressively abandoned his scientific work and handed over the work of the Observatory to his son, César-François.

Cassini, Jean-Dominique [known as Cassini IV] (1748–1845)

Astronomer, born at the Paris Observatory, great-grandson of the first director, grandson of the second, son of the third and himself the fourth, assuming the responsibilities of the directorship during the decline of his father, and the directorship itself in 1784. Persuaded King Louis XVI to restore the observatory, but the French Revolution occurred and Cassini, a monarchist, bitterly opposed the involvement of the new revolutionary government in observatory affairs and lost his position in 1793. Cassini IV spent his old age in his chateau, writing polemics justifying his own position and defending the scientific reputation of the family. The Paris Observatory had been in the charge of the Cassini dynasty for 120 years.

Cassini/Huygens Mission

The Cassini/Huygens mission is a planetary mission designed to explore in detail the Saturnian system. The mission is a joint undertaking between the United States National Aeronautics and Space Administration (NASA) and the EUROPEAN SPACE AGENCY (ESA). It was successfully launched from Cape Canaveral, Florida, on 15 October 1997 (figure 1) for a 7 yr interplanetary journey. The Cassini/Huygens spacecraft comprises the main craft, the Saturn Orbiter, and the Titan Probe, Huygens. The aim of the mission is to carry out a detailed study of the planet SATURN, its rings, satellites and magnetosphere. TITAN, Saturn's largest moon, is a prime target of the mission. A prime goal of the mission is also to study the relationships between the rings and the satellites, the interactions between the magnetospheric plasma and the satellites, the rings and the atmosphere of Titan. Cassini will study not only each part of the Saturnian system but also the system as a whole. The mission carries 26 scientific investigations, which include 18 instrument investigations, and eight interdisciplinary investigations that will rely on the data obtained by more than one instrument. The Saturn Orbiter carries onboard 12 scientific instruments while six instruments have been packed into the Huygens Probe.

Cassini/Huygens is an international undertaking. The planning for the Cassini/Huygens mission was started in 1984 when a joint ESA–NASA study was initiated. It required more than 6 yr of intensive studies and careful planning to allow both agencies to embark in 1990 on what is the most ambitious outer planet mission that has been undertaken so far. All together, 18 nations were involved during the hardware development phase. The ITALIAN SPACE AGENCY (ASI, Agencia Spatiale Italiana) has provided major elements of the Orbiter through a bilateral cooperation programme established with NASA in 1992. The 4 m High Gain Antenna is one of the elements contributed by ASI.

Figure 1. The launch of the Cassini/Huygens spacecraft on 15 October 1997 from Cape Canaveral, Florida.

The journey to Saturn takes 7 yr. Although Cassini/Huygens was launched by the most powerful rocket (Titan IVB/Centaur) that existed at that time, the 5.6 t spacecraft was too heavy to be launched on a direct trajectory to Saturn. The path of its journey includes several planetary encounters that are used for gravity-assist maneuvers to accelerate the spacecraft towards the next planet. The first three planetary encounters took place at Venus on 27 April 1998 and 24 June 1999 and at Earth on 17 August 1999. The last planetary encounter before Saturn will occur in late December 2000 at Jupiter. The Cassini/Huygens spacecraft will arrive at Saturn in July 2004. The nominal mission in the Saturnian system will last 4 yr. The Cassini/Huygens spacecraft will be placed in orbit around Saturn on 1 July 2004, when the Saturn Orbit Insertion (SOI) maneuver will take place. Five months after SOI, the Huygens Probe will be targeted and released from the Orbiter for its encounter with Titan 3 weeks later. In late November 2004, Huygens will enter and descend by parachute through the thick hazy atmosphere of Titan until it reaches the surface. Following the Huygens mission, the Cassini Saturn Orbiter will undertake its own mission of exploration of the Saturnian system in the course of 75 orbits around the planet. Forty-four of the orbits will include a close flyby of Titan at altitudes as low as 850 km above the surface, both for the purpose of making observations and for gravity-assist maneuvers. At the end of the mission, Titan will hold the record as the planetary body most used for gravity assist manoeuvres.

The mission is named in honor of the French–Italian astronomer JEAN-DOMINIQUE CASSINI. In the period 1671–85 he discovered four of Saturn's satellites as well as the large gap in the ring (the Cassini division) which is named after him. The Probe is named in honour of the Dutch astronomer CHRISTIAAN HUYGENS, who discovered Titan in 1655 while he was observing Saturn's rings. Huygens was also the first to explain the true nature of the rings.

The scientific objectives and the payload

The Cassini/Huygens mission will build on the discoveries made by the highly successful VOYAGER missions and will allow a quantum leap in the understanding of the

Saturnian system, the formation and evolution of a planetary system and the origin and evolution of the solar system as a whole. Titan, the largest moon of Saturn, and the second largest moon in the solar system after Jupiter's Ganymede, is a special target of the mission. Titan is a unique type of object in the solar system. It is shrouded by a thick methane-rich, hazy, nitrogen atmosphere. The surface pressure and temperature are 1.5 bar (1.5 times that

Aerosol Collector and Pyrolyzer (ACP)	France, Austria, USA	2 samples: 150–45 km, 30–15 km altitude	3-step pyrolysis: 20 °C, 250 °C, 650 °C
Descent Imager and Spectral Radiometer (DISR)	USA, Germany, France	Upward and downward spectra: 480–960 nm, 0.87–1.7 μm, resolution 2.4–6.3 nm; downward- and side-looking images, 0.66–1 μm; solar aureole photometry, 550 nm, 939 nm; surface spectral reflectance	Spectrophotometry, imaging, photometry, and surface illumination by lamp
Doppler Wind Experiment (DWE)	Germany, Italy, USA	(Allan variance)$^{1/2}$: 10^{-11} (in 1 s), 5–10^{-12} (in 10 s), 10^{-12} (in 100 s), corresponding to wind velocities of 2–200 m s^{-1}, probe spin	Doppler shift of Huygens telemetry signal, signal attenuation
Surface Science Package (SSP)	UK, Italy, USA, ESA–SSD	Acceleration: 0–100g Tilt: ±60° Temperature: 65–110 K Thermal conductivity: 0–400 m W m^{-1} K^{-1} Speed of sound: 150–2000 m s^{-1} Liquid density: 400–700 kg m^{-3} Refractive index: 1.25–1.45	Direct measurements using 'laboratory' methods: impact acceleration; acoustic sounding, liquid relative permittivity, density and index of refraction

on Earth) and 95 K (–178 °C). The tropopause temperature is 70 K at an altitude of 40–45 km. In the upper stratosphere the temperature rises up to 160–200 K. The 1 mbar level is reached in the altitude range 180–200 km. The photochemistry resulting from the photodissociation of methane and nitrogen in the atmosphere makes Titan a very fascinating body to explore. It may harbor complex organic molecules that are thought to be similar to the ones that were making the chemical soup of the young Earth before the appearance of life. The cold environment of Titan has frozen this pre-biological soup in an early state of its development. The exploration of Titan will allow us to investigate the complex chemistry at work in an environment similar to the one that may have prevailed on Earth after the end of the heavy bombardment, 3.8 billion years ago, before the appearance of life.

The scientific objectives of the Cassini/Huygens mission are categorized by the main mission targets.

With regard to the moon Titan:

to determine atmospheric composition, investigate energy sources for atmospheric chemistry, study aerosol properties and cloud physics; measure winds and global temperatures; determine properties of the surface and infer internal structure; investigate the upper atmosphere and ionosphere.

With regard to Saturn:

to determine global temperature and wind fields, cloud properties and atmospheric composition and infer properties of the deep atmosphere; study properties of ionosphere; provide observational constraints on scenarios of Saturn's formation and evolution.

With regard to the ring system:

to study the configuration of the rings and the dynamical processes responsible for their structure; map ring composition and particle size distribution; study

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

interactions between the rings and Saturn's magnetosphere, ionosphere, atmosphere and satellites.

With regard to the icy satellites:
to investigate the composition and distribution of surface materials and define mechanisms of crustal and surface modifications; determine the general characteristics of the satellites, including placing constraints on bulk composition and internal structures; investigate interactions with the magnetosphere.

With regard to Saturn's magnetosphere:
to determine the configuration of the magnetic field; determine properties, including sources and sinks of magnetospheric charged particles; investigate the interaction of the magnetosphere with the solar wind and with Titan's atmosphere and ionosphere.

The Orbiter and the Probe payloads are listed in tables 1 and 2 respectively, in which we also give a brief description of the measurements that will be made and what will be studied. Interdisciplinary investigations that will require data from more than one instrument to be conducted are listed in table 3. An overview of the observations that are planned in the Saturnian system is described below.

The planned observations

Titan

The moon Titan is a prime target of the Cassini/Huygens mission. With a diameter of 5150 km, Titan is the second-largest satellite of the solar system after Jupiter's Ganymede (5262 km). It is larger than the planets Mercury (4878 km) and Pluto (2300 km) and the Earth's moon (3476 km). Titan has a thick, hazy atmosphere which obscures the surface at visible wavelengths. The Huygens Probe will measure the physical properties and determine the composition profile of the atmosphere of Titan. Huygens will also make images of the surface and measure its composition along the descent track. The resolution of the images will improve as the Probe approaches the surface. Near the surface, details of less than 1 m, perhaps even less that 10 cm, should be observable. A radar altimeter will measure the surface topography below the Probe. The wind profile will also be measured. The Cassini Saturn Orbiter and the Huygens Probe will explore Titan with a complementary approach. Each time the Orbiter flies by Titan, it will perform a set of atmosphere and surface remote-sensing observations. The surface of Titan will be mapped by the Orbiter's Titan radar mapper and possibly optical instruments that may be able to see the surface through 'atmospheric windows' in the 0.8–2 μm range. The Orbiter observations will be designed to provide global coverage of Titan's atmosphere properties and of the surface; they will also include re-observations of the atmosphere and surface along the flight path of the Probe.

Table 3. Interdisciplinary investigations.

IDS investigation	*Participating country*	*Brief objectives*
Magnetosphere and plasma	France	Study of plasma circulation and magnetosphere–ionosphere coupling
Rings and dust	USA	Study of rings and dust within the Saturnian system
Magnetosphere and plasma	USA	Study of the plasma environment in Saturn's magnetosphere
Atmospheres	USA	Study of the atmospheres of Titan and Saturn
Satellites	USA	Study of the satellites of Saturn
Aeronomy and solar wind interaction	USA	Study of aeronomy in the Titanian and Saturnian atmospheres
Titan atmosphere–surface interactions	USA	Study of Titan's atmosphere–surface interaction
Titan aeronomy	France	Study of Titan's aeronomy
Titan organic chemistry	France	Study of Titan's organic chemistry

Planet Saturn

Cassini will measure the physical properties of the atmosphere of Saturn and determine its composition all around the globe as a function of altitude. The properties of the ever-changing clouds will be investigated and the global circulation of the atmosphere will be studied. The fast rotation of the planet (10 h 12 min) will allow us to study repeatedly the diurnal variations of atmospheric properties. Because of the alignment of the planet's dipolar axis with its rotation axis, Saturn's magnetic field is different from that of the Earth, Jupiter, Uranus and Neptune. The generation mechanism of Saturn's magnetic field is a prime topic for study (see also SATURN: MAGNETOSPHERE). The detailed study of Saturn's magnetism will allow us to probe the interior of the planet and to understand better how the dynamo effect works inside planet Earth. The interior of the planet will also be probed by gravity measurement techniques based on the precise measurement of the spacecraft's trajectory above the planet. This will allow us to place constraints on the interior of the planet.

Rings

Saturn's famous rings will be imaged under all solar phase angles and from different geometrical perspectives. The configuration of the rings will be observed and the composition and the dynamical processes responsible for the ring structure will be inferred from images and occultations at optical and radio wavelengths. The rings are

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

thought to be composed mainly of water ice particles. The compositional variation of the rings is thought to be due to different types of impurities in the ice. The size distribution and the chemical composition of the ring particles will be obtained. Direct, *in situ* measurements of the dust and meteoroid particles within the rings will be obtained by Cosmic Dust Analyzer. An objective of Cassini is also to search for new moonlets within the rings and to study the interrelation between the rings and satellites, including the imbedded satellites. (See also SATURN: RINGS.)

Icy satellites

The icy satellites offer many new worlds to explore. Saturn has 18 known moons. Cassini will image and map their surfaces over the course of the orbital tour. This will allow us to obtain the composition and distribution of surface material. A major goal of the mission is to study the geological history of the satellites and to study the mechanisms responsible for the modification of their surfaces. Detection of the internal magnetic fields of the satellites is also an important objective of Cassini as Galileo at Jupiter has shown that surprises are to be expected. Radio measurements of the spacecraft's trajectory during each satellite flyby will allow us to infer their bulk compositions and to place constraints on their internal structures. Cassini will search for organic material on the satellite surfaces. One major goal of Cassini is to study the relationship between the icy satellites and the rings. Similarities in composition between the satellites and the rings will be searched for. Cassini will also search for and, if found, characterize the tenuous atmospheres around Saturn's moons. (See also SATURN: SATELLITES.)

Although the full operational capabilities of the Cassini/Huygens spacecraft and of the ground system will only be available 2 yr prior to arrival at Saturn, some cruise science and observations during each planet flyby (Venus, Earth–Moon, Jupiter) were carried out.

A specific science objective has been included in the Cassini/Huygens mission that will take advantage of the inclusion of both X-band and Ka-band uplink and downlink capabilities of the telecommunication subsystem. It will allow the search for gravitational waves to be supported. The gravitational wave experiments will be conducted for periods of at least 40 days duration; they have been scheduled during the three oppositions after the Jupiter flyby in December 2001, December 2002 and January 2004.

The Cassini/Huygens spacecraft

The Cassini/Huygens spacecraft (figure 2) is the largest and most complex outer planetary spacecraft ever built. It is twice the size of the Galileo spacecraft, which is currently exploring the Jovian system; it is 6.8 m tall and 4 m wide. Its launch mass, including Huygens, was 5650 kg. More than half of its launch mass was propellant (3130 kg).

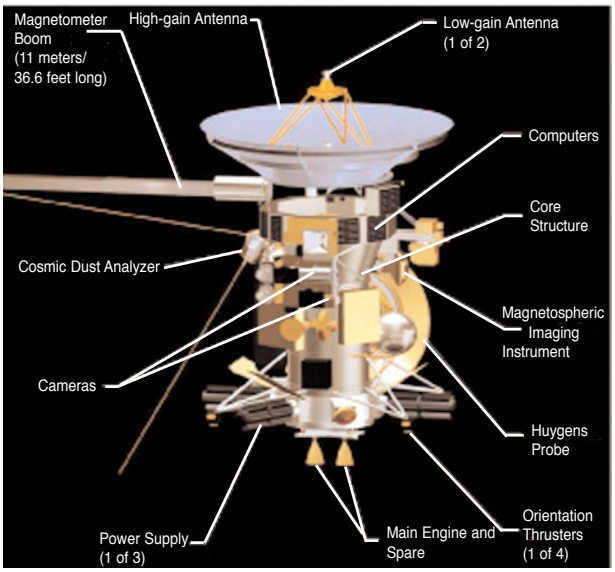

Figure 2. The Cassini/Huygens spacecraft.

The Saturn Orbiter

The Orbiter is a three-axis-stabilized spacecraft. The main body is formed by a stack consisting of the lower equipment module, the propulsion module, the upper equipment module and the High-Gain Antenna (HGA). Attached to this stack are the remote-sensing pallet, which carries the optical payload instruments, the fields-and-particles pallet, which carries most of the plasma particle and the dust instruments, and the Huygens Probe, attached sideways to the propulsion module. Electronic equipment of the radar is attached to the upper equipment module. The long electric antenna (shown in the deployed configuration) and the magnetic antennas of the Radio and Plasma Wave Subsystem (RPWS) are attached to the bottom part of the upper equipment module. The magnetometer boom canister is attached on the upper part of the upper equipment module, below the HGA. The 11 m long magnetometer boom is shown in its deployed configuration in the figure. The electrical power is provided by three Radioisotope Thermoelectric Generators (RTGs) which deliver more than 700 W of electrical power. The spacecraft electronics bus and several instrument electronics subsystems are housed in the upper equipment module which is thermally regulated to provide a benign (~10–20 °C) environment. While in the inner solar system, the spacecraft flies with its HGA pointed at the Sun, using it as a sunshade. At Saturn, using its 20 W X-band transmitter and its 4 m HGA, the spacecraft will be able to communicate with NASA's Deep Space Network at data rates up to 166 kbit s^{-1}. Two Low-Gain Antennas (LGAs) transmit, at a low rate (minimum 40 bit s^{-1}) data and receive telecommands when the HGA cannot be pointed at Earth.

For propulsion and maneuvers, on its way to Saturn and during the Saturn orbital phase, the Orbiter uses one of the two redundant 445 N engines and 16 smaller 0.5 N thrusters clustered in groups of four in redundant pairs. The gimbal mechanisms of the main engines allow their thrust to be directed through the spacecraft's center of gravity. The main engines use the helium-pressurized hypergolic combination of monomethyl hydrazine ($N_2H_3CH_3$) fuel and nitrogen tetroxide (N_2O_4) oxidizer. The thrusters use hydrazine (N_2H_4). The main engines are covered by a retractable cover when not in use.

The Orbiter Command and Data Subsystem (CDS) receives ground commands via the Radio Frequency Subsystem (RFS). The CDS distributes the commands to the other subsystems, to the Orbiter payload instrument or to the Probe (when attached to the Orbiter). In turn, the CDS collects data from other subsystems, the Orbiter payload or the orbiter-mounted Probe Support Equipment and transfers them to one of the two redundant 1.8 Gbit Solid State Recorders (SSRs). The CDS subsequently retrieves those data from the SSR, formats and delivers them to the RFS for transmission to Earth via either the HGA or one of the two LGAs.

Dynamic control of the orientation of Cassini is provided by the Attitude and Articulation Control Subsystem (AACS). When high spacecraft stability is required, the spacecraft rotation is controlled by Reaction Wheel Assemblies (RWAs). The thrusters are used when fast rotation or acceleration rates are required. The AACS uses two redundant Inertial Reference Units (IRUs), two redundant Stellar Reference Units (SRUs) and a Sun Sensor Assembly (SSA). The AACS is capable of supporting a pointing accuracy of 1 mrad (3.4 arcmin) with a stability of 8 μrad (0.2 arcsec) and rotation rates of 0.02°–1° s^{-1}.

Thermal control of the Orbiter is accomplished by several means, the most visible being the black-and-gold Multi-Layer Insulation (MLI). In addition, the thermal control uses louvers positioned on the 12-bay electronics bus, electric heaters and Radio-isotope Heater Units (RHUs) and heat radiators. The infrared instruments (VIMS and CIRS) are thermally insulated from the spacecraft bus and they provide their own thermal control as an integral part of the instrument.

The Huygens Probe

The Huygens Probe is an entry probe. It has a mass of 330 kg. It comprises two main elements: the entry protection system and the descent module that is enclosed in it. The main elements of the Huygens Probe are shown in figure 3. The probe is attached sideways to the Saturn Orbiter (see figure 2). The Probe separates from the Orbiter with a relative velocity of 0.3 m s^{-1} and a spin rate of 7 rev min^{-1}, which provides stability during the 22 day coast to Titan and during the atmospheric entry. The entry subsystem consists of the front heat shield, which has a diameter of 2.75 m, and the after cover, both covered with silicate-based thermal-protection material for protecting the entry module from the radiative and convective heat fluxes (up to 1 MW m^{-2}) generated during the entry phase in the altitude range 350–220 km, where the Probe decelerates from about 6000 m s^{-1} down to 400 m s^{-1} (Mach 1.5) in less than 2 min. At Mach 1.5, at an altitude of about 170 km, the parachute-deployment sequence is initiated by a pyrotechnic device which pulls out the 2.59 m diameter pilot chute to pull the back cover away from the rest of the assembly. As it goes, the back cover pulls the 8.3 m diameter main parachute from its container. This canopy inflates during the supersonic phase to decelerate and stabilize the Probe through the transonic regime. The front shield is released at about Mach 0.6, 30 s after inflation of the main parachute. In fact the main parachute is sized to provide sufficient deceleration to guarantee a positive separation of the front shield from the descent module.

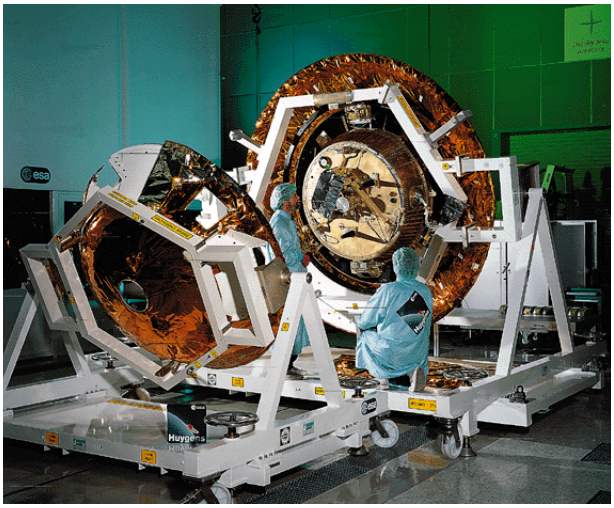

Figure 3. The Huygens Probe during final integration in Europe before it was shipped to NASA's Kennedy Space Center for the integration activities with the Cassini Saturn Orbiter.

Cassini/Huygens mission overview

The Cassini/Huygens spacecraft was launched at 08:43 GMT on 15 October 1997 by a Titan IVB/Centaur rocket from Cape Canaveral Air Force Station in Florida. The 5.6 t spacecraft was too heavy to be injected directly into a Saturn-approach trajectory; it requires several planetary boosts to reach its destination. The interplanetary trajectory (figure 4) includes gravity assists from Venus (26 April 1998 and 24 June 1999), Earth (18 August 1999) and Jupiter (30 December 2000).

Arrival at Saturn of the Cassini/Huygens spacecraft is planned to take place on 1 July 2004. At this point, a major maneuver will be executed while the spacecraft crosses the ring plane. The main engine will

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

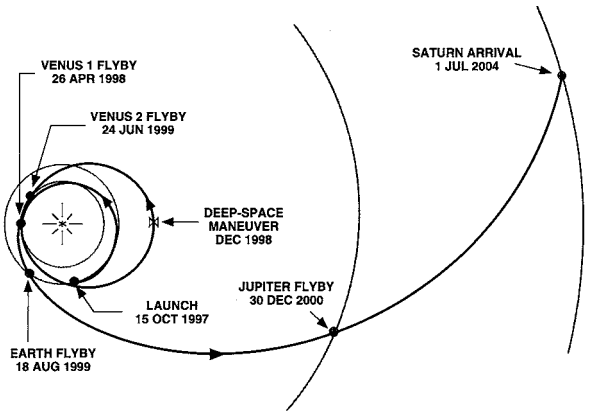

Figure 4. The interplanetary trajectory of the Cassini/Huygens spacecraft.

burn for about 90 min to slow down the spacecraft so that it will be captured in orbit around Saturn. The Probe is to be released from the Saturn Orbiter at the end of the initial orbit around Saturn, nominally 22 days before Titan encounter. Prior to releasing the Probe, the Orbiter is targeted on a collision trajectory with Titan as the Probe has no maneuvering capability by itself. Shortly after Probe release, the Orbiter will perform a deflection maneuver, so as not to enter the atmosphere of Titan. This maneuver will also set up the radio communication geometry between the Probe and the Orbiter for use during the Probe descent. It will will also set up the initial conditions for the subsequent satellite tour which starts after completion of the Probe mission.

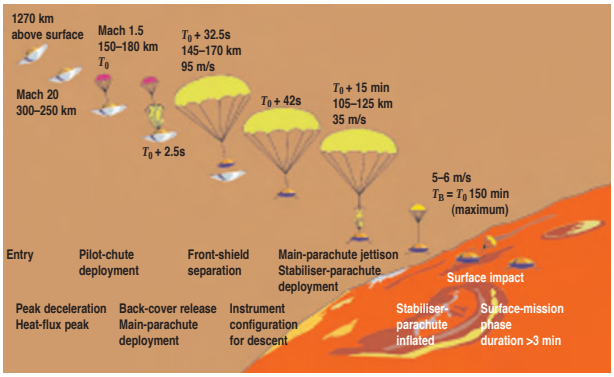

Figure 5. The Huygens entry and descent scenario.

Huygens' entry into the Titan atmosphere is planned for 27 November 2004. The descent under parachute will take a maximum of 2½h. On the way down, Huygens will measure the physical and the chemical properties of the atmosphere and take images of the surface underneath the Probe. During its descent and possibly for a short period on the surface, the Probe will radio the data acquired to the Cassini Saturn Orbiter, which will receive them via its HGA pointed at Titan. The Orbiter will in turn send the data back to Earth after the Huygens mission is over, also using its HGA, then pointed at Earth. The Huygens entry and descent scenario is illustrated in figure 5.

After completion of the Probe mission, the Saturn Orbiter will start its 4 yr tour of the Saturnian system, the so-called satellite tour. In the current mission scenario, it consists of more than 70 Saturn-centered orbits, connected

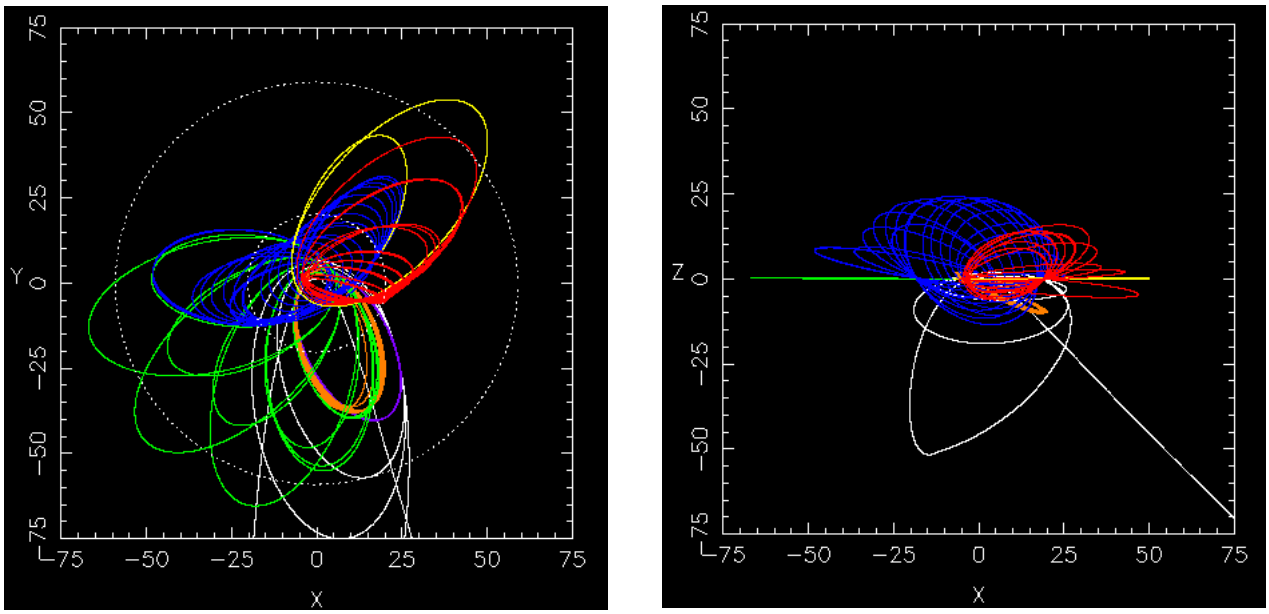

Figure 6. Baseline satellite tour in the Saturnian system; on the left side the projection of the trajectory is shown in the equatorial (X–Y) plane of Saturn, while on the right side the projection perpendicular to the equatorial (X–Z) plane is shown. Dimensions in X, Y, Z are indicated in Saturn radii (1 Saturn radius (R_S) = 60 330 km). Note that the apoapsis of the first orbit lies at ~170R_S, beyond the limit of the figure.

by Titan gravity-assist flybys or propulsive maneuvers. The size of these orbits, their orientation to the Sun–Saturn line and their inclination to Saturn's equator are dictated by the various scientific requirements, which include Titan ground-track coverage, icy-satellite flybys, Saturn, Titan or ring occultations, magnetosphere coverage, orbit inclinations and ring-plane crossings. The geometry of the tour is illustrated in figure 6.

The flight operations

The flight operations of the Cassini/Huygens mission operations are carried out at the JET PROPULSION LABORATORY (JPL) in Pasadena, California. The uplink and the downlink operations are carried out from the Mission Control Center at JPL. The data are collected via NASA's deep space network and stored on computers at JPL, where the spacecraft's health and status are routinely assessed. The Cassini/Huygens operations are based on a distributed operations concept. In this concept, the instrument teams analyse their instrument data and prepare instrument operation sequences from their home institutes and transmit them to JPL for uplink. During the main mission, from the start of the Saturn encounter until the end of the mission, the Orbiter instrument teams will interact daily with the spacecraft operations team at JPL. The flight operations of the Huygens Probe are carried out from ESA's Operations Center at ESOC in Darmstadt, Germany, where the Huygens Probe Operations Center (HPOC) has been established. All Huygens-related mission activities (periodic in-flight checkouts and Probe mission phase) are carried out from the HPOC. The Huygens telemetry data are routed to the HPOC, where they are processed and distributed to the Huygens investigators.

Jupiter flyby

The Cassini spacecraft has made a successful flyby of Jupiter during a gravity-assisted swing toward Saturn and in addition has been used to try out some of its instrumentation, making important scientific observations of Jupiter and its moons. The Cassini observations were made in conjunction with observations by the Galileo spacecraft, also orbiting Jupiter. The observations by the two spacecraft were complemented by nearly simultaneous images from the Earth-orbiting Hubble Space Telescope and Chandra x-ray Observatory. Earth–based radio and optical telescopes were also used.

The Galileo spacecraft has been in orbit around Jupiter since December 1995 while Cassini observed Jupiter from 1 October, 2000 to 31 March 2001. Cassini made its closest approach on 30 December 2000, at a distance of about 9.7 million kilometers (6 million miles). This gave Cassini a boost from Jupiter's gravity that accelerated the spacecraft by about 2 km s^{-1} (about 4500 miles per hour) and will enable it to reach its ultimate destination, Saturn, in July 2004 for the planned four-year study.

A higher–than–normal drag that was detected on one of Cassini's reaction wheels did not reappear. The reaction wheels are used to rotate the spacecraft in different directions, and the problem led to suspension from 19 December to 28 December of scientific observations that would have required pointing the spacecraft, such as for taking pictures. Only two experiments, the Ion and Neutral Mass Spectrometer and Radio Science, and the Huygens probe for studying Saturn's moon Titan, did not take data during the study of Jupiter.

Observational results include revealing new data on the dynamics of Jupiter's magnetosphere, its radiation belts, aurorae and its interactions with the solar wind. See JUPITER, JUPITER: SATELLITES, JUPITER: RADIO EMISSIONS, JUPITER ATMOSPHERE, IO: PLASMA TORUS.

Web update (31 October 2002)

During July 2002, NASA's Cassini spacecraft took test images of a star that reveals successful results from an extended warming treatment to remove haze that collected on a camera lens during 2001. The quality of the new images is virtually the same as star images taken before the haze appeared. In the most recent treatment, the camera had been warmed to 4 degrees Celsius (39° F) for four weeks ending 9 July. Four previous treatments at that temperature for varying lengths of time had already removed most of the haze. The camera usually operates at –90° C (–130° F).

Cassiopeia

(abbrev. Cas, gen. Cassiopeiae; area 598 sq. deg.) A northern constellation which lies between Cepheus and Andromeda, and culminates at midnight in early October. It is named after Queen Cassiopeia, wife of King Cepheus and mother of Andromeda in Greek mythology, and is usually shown on early celestial charts as a seated figure. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A conspicuous constellation, Cassiopeia is easily recognized by the characteristic letter 'W' (or 'M') formed by its five brightest stars: ε (mag. 3.4), δ (Ruchbah, mag. 2.7), γ (mag. 2.2), α (Shedar, mag. 2.2) and β (Caph, mag. 2.3). There are three other stars of magnitude 4.0 or brighter. γ Cassiopeiae, the central star of the 'W', is a rapidly rotating irregular variable, which spasmodically throws off a shell of material from its equatorial zone and simultaneously fades by up to 1.4 magnitudes. Other interesting variables are R Cassiopeiae, a Mira-type star (range 4.7–13.5, period about 430 days), and RZ Cas, an eclipsing binary (range 6.2–7.7, period 1.2 days). η Cassiopeiae is a fine binary with yellow (G0) and red (M0) components, magnitudes 3.5 and 7.4, separation 12.5″.

The Milky Way passes through Cassiopeia and the constellation contains a number of open star clusters, including M52 (NGC 7654), which contains more than 100 stars between ninth and twelfth magnitude, M103 (NGC 581), which contains about 40 stars between magnitudes 8 and 12, and NGC 225, which has about 20 stars fainter than ninth magnitude. Cassiopeia is also the 'graveyard' of the supernova represented by the powerful radio source Cassiopeia A and of that observed by the Danish astronomer Tycho Brahe (1546–1601) in 1572.

See also: Cassiopeia A, Tycho's star.

Cassiopeia A

The brightest radio source in the constellation of Cassiopeia and the brightest cosmic radio source in the entire sky. It is a supernova remnant, an expanding cloud of gas that was ejected in a catastrophic stellar explosion. From the present size and rate of expansion of the cloud, the explosion that created it must have occurred around the year 1660. Cassiopeia A lies at a distance of about 10 000 light-years. At that distance, a typical supernova should attain a peak brightness greater than that of the brightest naked-eye star and perhaps comparable to the planet Venus, but no bright 'new star' was recorded in Cassiopeia at around that time. For whatever reason, the supernova that produced Cassiopeia A must have been of unusually low optical luminosity.

Although not conspicuous in visible light (only a few faint wisps of nebulosity can be seen) Cassiopeia A radiates across the electromagnetic spectrum from x-ray to radio wavelengths. Its intensity, or flux density, at a wavelength of 20 cm in the radio region, is 2477 janskys, and its angular diameter is about 5 arc minutes.

Castelli, Benedetto (1578–1643)

Mathematician, born in Brescia, Italy, Benedictine monk, professor at Padua. GALILEO's closest scientific collaborator, he defended, and edited Galileo, he helped his sunspot research, inventing the method of projection so as to view safely the Sun's image with a telescope. His book on hydraulics, *Della Misura dell'Acque Correnti, or On the Measurement of Running Waters*, founded modern hydrodynamics.

Castor

The star α Geminorum, apparent magnitude 1.58. This is in fact a very complex multiple star system. Observed with a moderately powerful telescope it is seen to be double. The components of this binary system are a pair of white stars, α Gem A (apparent magnitude 1.9, spectral type A1V), and α Gem B (3.0 and A2V). Their current separation is 3.1″ at position angle 76°; the period is 420 years. Each of these component stars is itself a spectroscopic binary, their periods being 2.9 days (α Gem A) and 9.2 days (α Gem B).

The system has another more distant component, α Gem C (the variable star YY Geminorum), 72.5″ distant at position angle 164°. This is an eclipsing binary, its components being a pair of red dwarfs of spectral type M1, their combined magnitude varying between 9.2 and 9.6 in a period of 19.6 h. Although part of the gravitational system, this component is so far from the main pair—about 1000 astronomical units—that its orbital period must be of the order of a million years.

This sextuple star system is situated 52 light-years away, and has a parallax of 0.063″; the combined absolute magnitude of the principal components is 0.6.

Cat's Eye Nebula (NGC 6543)

A planetary nebula in the constellation Draco, position RA $17^{h}\ 58.6^{m}$, dec. $+66^{\circ}\ 38.0'$, named for its oval shape and greenish color. It is about $20''$ in diameter, and of ninth magnitude; the central star is tenth magnitude. William Huggins' spectroscopic observation of the Cat's Eye in 1864, revealing a spectrum consisting of three bright lines, provided proof that not all 'nebulae' consist of stars.

Cataclysmic Binaries: Classical and Recurrent Novae

The Latin word *nova*, meaning 'new', was applied historically to the sudden appearance of a bright star, not previously recorded. Such *novae stellae* appear in Eastern records from about 1500 BC and in European records in the past three centuries (many, however, are ancient SUPERNOVAE). The discovery of a different kind of nova, dwarf novae, in the mid-nineteenth century, led to the use of *classical* nova for the original type. Until 1887, when fainter novae began to be discovered by wide-field photography, only six novae had been found in the post-telescopic era. The brightest of these were Nova Vulpecula 1670 (magnitude 2.6 at maximum), Nova Ophiuchi 1848 (mag. 4.2) and Nova Cygni 1876 (mag 3.0).

Post-outburst observations of Nova Oph showed that after a few years it faded to magnitude 13.5, which demonstrated that whatever the cause of the dramatic nova explosion, it had not destroyed the star altogether. The realization that some novae have repeated eruptions (e.g. Nova Corona Borealis in 1866 and 1946) underlined the fact that the process is *cataclysmic*, rather than catastrophic. With current understanding of the cause of eruptions (see below) it is believed that all novae must be recurrent, and that all types of cataclysmic variable must regularly become novae, but the intervals between eruptions are in general much greater than the few centuries of recorded history.

At their brightest, novae typically reach absolute magnitude $M_v \sim -9$, which would make them easily detectable throughout our Galaxy were it not that novae are concentrated towards the Galactic Plane and Galactic Center, which causes strong interstellar extinction of the light from the most distant novae. As a result, although there may be as many as ~80 novae per year erupting in the Galaxy, on average only about three per year are detected. In the Magellanic Clouds and the Andromeda Galaxy (M 31) novae are readily discovered (at maximum being at apparent magnitudes $m_v \sim 10$ and ~15 respectively) and with large ground-based telescopes and CCD detectors novae can be studied even in the Virgo cluster of galaxies, at brightest magnitude $m_v \sim 23$.

A list of novae that reached apparent magnitude 3.0 or brighter is given in table 1. Variable star designations are used in table 1; for example, Nova Herculis 1934 is also known as DQ HERCULIS.

Light curves of novae

The variation of apparent visual brightness during a nova eruption is the most straightforward of measurements to make. Although it is rare to discover a nova much before its maximum brightness, the rise can sometimes be delineated through the chance appearance of the nova on wide-field photographic survey plates. There is a wide range of speeds with which novae pass through their eruption behavior, but all can be approximately described by the schematic curves shown in figure 1.

The initial rise of typically 6–13 magnitudes occurs in one or two days, often with a temporary halt lasting a few hours for fast novae to a few days for slow novae, before a less steep final rise of ~2 mag to maximum. The early decline is smooth for all but the slowest novae, where irregular variations are seen. The *speed class* of a nova is defined by the rate at which the early decline takes place. This is measured as the time t_2 or t_3 taken to fall 2 or 3 magnitudes respectively; the definitions are listed in table 2.

Table 2. Speed classes of novae.

Speed class	t_2 (days)
Very fast	<10
Fast	11–25
Moderately fast	26–80
Slow	81–150
Very slow	151–250

Starting about 3 magnitudes below maximum visual luminosity, through a ~2.5 magnitude drop known as the transition region, novae show a variety of behaviors. Some, particularly the faster novae, continue to decline smoothly. Others pass through a deep minimum, as deep as 7–10 mag, lasting 2 to 3 months, after which the smooth decline continues. Others show quasi-periodic brightness variations with amplitudes 1-1.5 mag and quasi-periods typically in the range 5–25 days.

The final decline to the post-nova is usually smooth, but in a few cases dwarf nova outbursts can begin late in the decline (e.g. Nova Per 1901, which commenced 2–3 mag outbursts in 1950, with intervals of ~2 years).

Absolute magnitudes of novae at maximum brightness, M_v(max), can be found if the distances and interstellar extinctions can be determined. The expansion parallax (see below) for some individual novae, supplemented with maximum brightnesses of novae in the Magellanic Clouds and M31, show that there is a strong correlation between t_2 and M_v(max) or M_{pg}(max) (for blue region photographic magnitudes) known as the 'absolute magnitude versus rate of decline relationship'. This may be expressed by the equation $M_{pg}(\max) = 3.35 \log t_2 - 12.2$. Application of this relationship gives a valuable method of finding the distances to extragalactic systems in which novae occur. Another technique uses the fact that all novae, almost independent of speed class, reach $M_v \sim -5.5$ 15 days after maximum light.

Satellite observations of the ultraviolet brightnesses of novae show that the peaks of the flux distributions move steadily to shorter wavelengths after maximum light. The early decline in visual luminosity is due almost entirely to this redistribution of flux towards ultraviolet wavelengths.

Infrared light curves of novae behave very differently from visual light curves. The infrared flux grows slowly during the initial decline and increases greatly if there is a deep minimum during the transition region. The flux distribution of the IR component is typical of emission

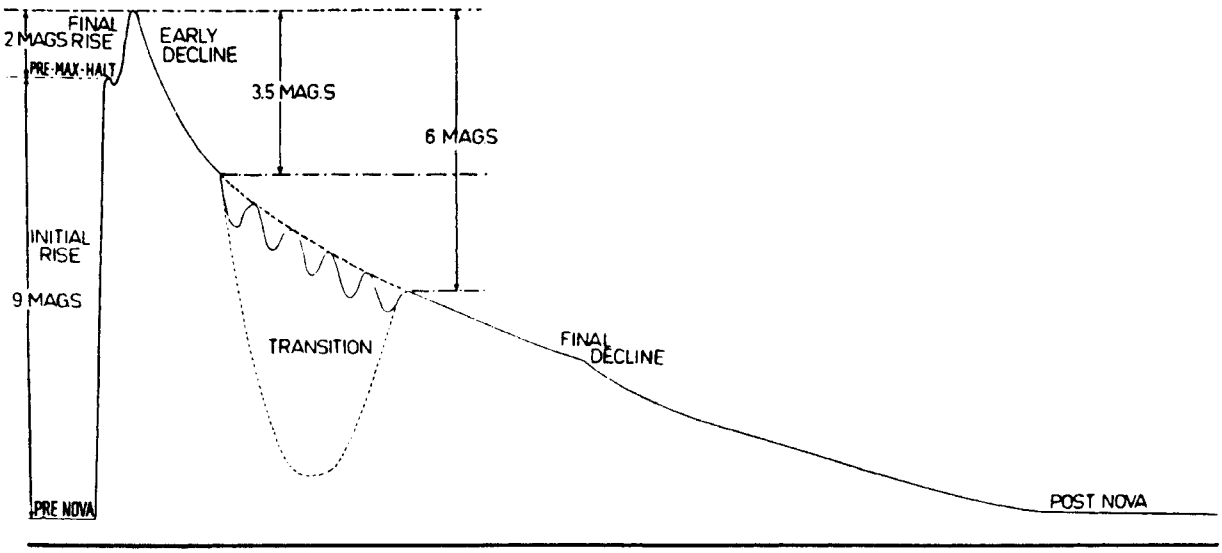

Figure 1.

from dust grains with temperatures ∼1000 K, and is interpreted as absorption of short-wavelength radiation as dust grains grow in expanding and cooling gas ejected by the nova explosion. In extreme cases the dust becomes optically thick in the visible, causing the deep visual minimum.

Adding the visual, ultraviolet and IR fluxes shows that the visual light curve of a nova is very misleading: the total luminosity of a nova in fact remains almost constant at least until well into the transition region. These 'plateau' luminosities of novae during the early phases lie in the range (2–4) $\times$ 10^4 $L_\odot$. These are roughly the Eddington luminosities for stars of about one solar mass. The short-lived peak luminosity can be a few times higher still, especially for fast novae. These observations show that radiation pressure is probably the motivating force for the ejection of gas during a nova explosion.

Spectra of novae

On the final rise to maximum light the spectrum of a nova resembles that of a supergiant; the spectral class is of early B type, moving to later type and reaching about A5 at maximum. The lines are very broad and there is a shortward Doppler shift of the wavelengths; both the shifts and the widths are (1–2) $\times$ 10^3 km s^{-1}, indicating a rapidly expanding optically thick shell. P Cygni line profiles are often seen, again pointing to an expanding shell. After maximum light the changes in spectrum are quite complex, indicative of several expanding envelopes with different velocities. On the initial decline a set of absorption lines resembling an A or F type supergiant, with a blueshift greater than that of the pre-maximum spectrum, develops. This is known as the *principal spectrum*; its velocity displacement is strongly correlated with speed class, with velocities up to 4000 km s^{-1} for the very fast novae and as low as 100 km s^{-1} for the slowest. The absorption

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

lines often show multiple structure, indicative of many subshells or blobs of gas being present in the expanding shell.

Soon after maximum light the strongest lines develop P Cyg profiles and large numbers of emission lines appear, chiefly of H, Ca II, Na I and Fe II in the visible. Later, the principal spectrum (identified by its velocity shift) weakens and forbidden lines of [O I], [O II] and [N II] appear—these are characteristic of gas at low densities.

Another distinct suite of absorption lines—the *diffuse enhanced spectrum*—appears soon after the principal spectrum has become clear, but blueshifted at about twice that of the latter. Yet another system—the *Orion spectrum*—appears one to two magnitudes down from maximum, and is characterized by single components, displaced blueward at least as much as the diffuse enhanced system.

At a late stage in the nova eruption, a *nebular spectrum* develops, at first merely being strengthening of the principal spectrum's forbidden emission lines, but with the ultimate appearance of [O III], [Ne III], giving the nova spectrum an appearance similar to that of a PLANETARY NEBULA. In the highest energy novae successively higher stages of ionization are seen, up to ions typical of coronal conditions: e.g. lines from [Fe X] and [Fe XIV].

The evolution of a nova spectrum is generally understood as being generated by an expanding, inhomogeneous shell, ionized by an intense source of high-energy radiation (temperature 10^5–10^6 K) at its center. The latter must be the central star, heated by the explosion.

The spectra of novae can be used to determine the physical conditions and the chemical composition of the expanding shell. Novae typically show abundances of C, N, O, Ne, Mg and some heavier elements considerably enhanced compared with those of the Sun and other normal stars. The relative abundances differ among the novae; typical enhancements are factors of 10 to 100. The helium-to-hydrogen ratio is also often different from that in the Sun, being higher by up to a factor of 1.5 or lower by as much as a factor of 5. The higher abundance of carbon probably helps the formation of obscuring dust in some of the nova shells.

Many novae show greatly enhanced abundances of neon—sufficient for a class of *neon novae* to have been defined. Most neon novae are fast or very fast, but at least one (Nova Ophiuichi 1988) was a slow nova.

Nova shells

Evidence for ejection of a shell comes not only from the spectroscopically detected expansion, but also from direct imaging. The Hubble Space Telescope was able to resolve the shell of Nova Cygni 1992 467 days after eruption when the angular radius of the shell was only 0″.13. Radio emission from nova shells (in the 2–100 GHz frequency region) enables very long baseline interferometry (VLBI) also to image shells with angular resolutions down to 0″.1. Eventually, at least for relatively nearby novae, the shell may expand sufficiently that it can be seen directly in images made from the ground. Figure 2 shows the present

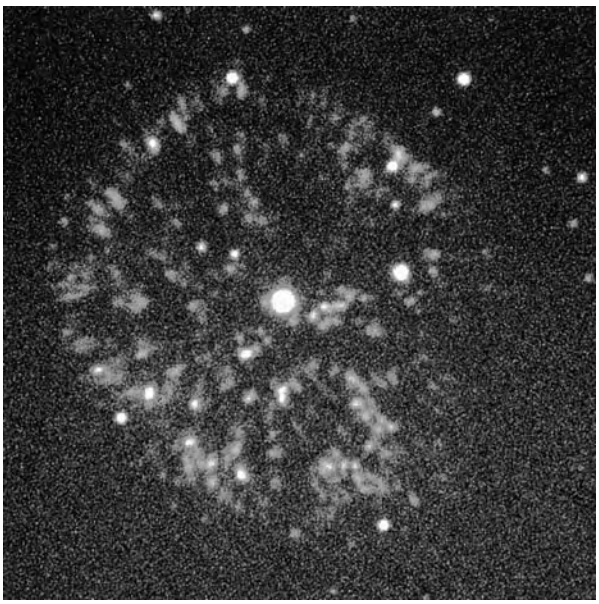

Figure 2.

appearance of Nova Persei 1901; the inhomogeneous structure is confirmed by such images. Many nova shells (e.g. Nova Herculis 1934) have more regular outlines, often elliptical in profile, showing that average ejection velocities vary systematically with direction. This is in accord with some spectroscopic analyses which detect 'equatorial' bands and 'polar' plumes ejected at different rates.

The angular rate of expansion directly measured by VLBI, or from the observed radius of the shell measured on photographs taken a known time (∼ decades) after the nova eruption, can be combined with the spectroscopic expansion velocity to determine the distance of a nova. From simple geometry, the *expansion parallax*, or its reciprocal, the distance d in parsecs, is given by $d = 0.20v/(\mathrm{d}\theta/\mathrm{d}t)$ pc, where v is the expansion velocity in km s^{-1} and $\mathrm{d}\theta/\mathrm{d}t$ is the rate of increase of angular radius, measured in seconds of arc per year. From this relationship we see that a nova at a distance of 1 kpc and expansion velocity 1000 km s^{-1} should show a shell of radius ∼4″ 20 years after eruption. However, with cooling of the central star, expansion away from this central exciting source, and decreasing surface brightness as the shell increases in area, most nova shells in fact cannot be imaged on the sky.

Analysis of the spectra of nova shells can provide estimates of the electron and ion densities in the regions where the emission lines are formed. If the total volume of the shell is known, this can give the total mass of the shell. However, the inhomogeneity of the shell leads to considerable uncertainty in how much of the apparent volume is actually filled with hot gas. Masses obtained spectroscopically lie in the range (1–30) $\times$ $10^{-5}M_\odot$. A possibly more reliable determination is obtained from the radio emission at a time when the shell has become

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

optically thin at radio wavelengths. Then all of the shell material contributes to the radio emission, and this arises from thermal (free–free) emission in the ionized shell. Shell masses determined this way are in the range (5–40) $\times 10^{-5} M_\odot$.

These ejected masses are compatible with the earlier statement that nova eruptions can occur many times in the life of a cataclysmic variable star: if the exploding star has a mass $\sim 1 M_\odot$, it can undergo hundreds or thousands of eruptions before depleting its mass significantly.

Before leaving nova shells, one other effect that may be directly imaged should be mentioned. For eight months after the eruption of Nova Persei 1901 nebulous patches were observed, apparently receding from the nova at ~20 arcmin per year. At the distance of that nova, this angular velocity corresponds to a linear velocity comparable to that of light. It was therefore concluded that the burst of light caused by the nova explosion was illuminating an interstellar dust layer in the vicinity of the nova. Such a phenomenon is known as a *light echo*, but has been seen for only two novae.

The physics of nova eruptions

As with all cataclysmic variables, novae are CLOSE BINARY STARS in which mass is being transferred from a star of normal dimensions (i.e. a main sequence star, or more rarely a giant), known as the secondary, onto a WHITE DWARF primary. At the time it was formed the white dwarf would have had no hydrogen in its interior, which would contain helium or carbon, oxygen or neon, magnesium, according to its mass. It is the continued accumulation of hydrogen-rich gas on the surface of the white dwarf that leads to the explosion that we recognize as a nova eruption.

Apart from an outer layer of about $10^{-4} M_\odot$, the interior of a white dwarf is degenerate. The essential physics of a nova explosion is contained in a comparison of the equation of state for degenerate matter, $P \propto \rho^\gamma$, with that for a perfect gas, $P \propto \rho T$, where P, ρ and T are respectively the pressure, density and temperature of the gas and γ is a constant. Suppose a region of the gas is heated slightly, then the pressure in a perfect gas increases and the gas can expand, thereby absorbing the heat. But the pressure in degenerate gas is independent of temperature, so no mechanical change takes place. If the temperature rises sufficiently, however, the Fermi temperature will be reached, above which the gas ceases to be degenerate—it becomes a perfect gas and its pressure will rapidly increase to match the density and temperature required by the change in equation of state.

Accumulation of hydrogen on the surface of the white dwarf builds a layer, the base of which becomes hotter and denser as it is compressed and is pushed deeper towards the hot interior. Nuclear reactions (at first the proton–proton chain, and later the CNO cycle) begin, which heat the gas. The mass $M_{\rm env}$ of the overlying layer sufficient to cause these nuclear reactions at its base depends quite sensitively on the mass of the white dwarf: it decreases from $\sim 1 \times 10^{-4} M_\odot$ at $0.6 M_\odot$ to $\sim 8 \times 10^{-7} M_\odot$ at $1.4 M_\odot$. This basal layer lies in a region of partial degeneracy, so the heating caused by nuclear reactions increases the temperature without expanding the layer. The increased temperature enhances the rate of energy production and a *thermonuclear runaway* ensues (as in a hydrogen bomb) until the Fermi temperature is reached and then the whole of the outer layer is blown into space. In many cases, a small part of the outer region of the degenerate core may be carried off in the explosion, creating the overabundances of C, O, Mg and Ne that are seen in some novae. Another cause of exceptional C, N or O abundances is that the explosion is so rapid that the CNO cycle does not reach the equilibrium that has produced the abundances of these elements present in normal stars.

If the rate at which mass is transferred from the companion star onto the white dwarf is $\mathrm{d}M/\mathrm{d}t$, then the time between eruptions will be $M_{\rm env}$ divided by $\mathrm{d}M/\mathrm{d}t$. Average mass transfer rates in cataclysmic variables are estimated to be $\sim 5 \times 10^{-9} M_\odot$ yr^{-1}, so the values of $M_{\rm env}$ given above imply intervals of $\sim 2 \times 10^4$ yr for a $0.6 M_\odot$ white dwarf and ~160 yr at $1.4 M_\odot$. We deduce that the observed recurrent novae occur probably at the high-mass end of a spread of white dwarf masses.

Computations of the evolution of a nova shell, using hydrodynamic computer codes, incorporate the initial expansion as the basal layer exceeds its Fermi temperature, plus the effects of the shock wave that occurs in the most energetic explosions, and the effect of radiation pressure. The resulting models match the observed range of nova behaviour quite well (e.g. the constant Eddington luminosity plateau of a nova eruption was predicted before it was observed). The models also show super-Eddington luminosities before the plateau. Early models failed to reproduce the duration of eruption and the decline branch of the eruption light curve, but these are now explained by interaction of the revolution of the secondary star in orbit: this transfers energy and angular momentum to the expanding shell (which forms a common envelope around the central binary) and leads first to a sustained wind phase and then to rapid shut down.

The diffuse enhanced and Orion absorption line systems seen in spectra of erupting novae have been interpreted as evidence for continued ejection of gas after the initial explosive phase. This also is present in the models: the high luminosity of the heated white dwarf produces a RADIATIVELY DRIVEN STELLAR WIND.

As the expanding envelope reduces in density and becomes more transparent it is possible to see further into it, allowing progressively hotter regions to be detected. This is the reason why the peak of the flux distribution moves into the ultraviolet in the early phases of a nova eruption. The freshly revealed surface of the white dwarf can have a temperature $\sim 10^6$ K; a $1.25 M_\odot$ white dwarf will then cool to 50 000 K in about 300 years.

The origin of the quasi-periodic oscillations that occur in some novae during the transition region (figure 1) is not certain; they may be radial pulsations of the envelope that surrounds the central binary star.

Table 3. Recurrent novae.

Star	Dates	Magnitude at maximum	Magnitude at minimum	t_2 (days)
T CrB	1866, 1946	2.0	11.3	3.8
V394 CrA	1949, 1987	7.0	18.8	3.3
RS Oph	1898, 1933, 1958, 1967, 1985	4.3	12.5	4
T Pyx	1890, 1902, 1920, 1944, 1966	6.5	15.4	62
V3890 Sgr	1962, 1990	8.4	17.2	9
U Sco	1863, 1906, 1936, 1979, 1987	8.8	18.5	2.0
V745 Sco	1937, 1989	9.7	21	6.6
LMC-RN	1968, 1990	10.9	20	3

Recurrent novae

Only eight novae are currently known to be recurrent (a few other stars were once thought to belong to this class, but have proved either to be large-amplitude, long-recurrence interval dwarf novae, or are novae which later had dwarf nova outbursts). These are listed in table 3. One of these is in the Large Magellanic Cloud.

There are three subclasses of recurrent novae. The first, comprising T CrB, RS Oph, V3890 Sgr and V745 Sco, all have giant secondaries of M spectral type and hence orbital periods greater than 100 days (an M giant could not fit in a binary of shorter period). From the brevity of eruptions it is possible that some of their eruptions this century have been overlooked. The T CrB stars obey the M_v(max)–t_2 relationship. Their short recurrence times are partly due to the high rate at which giant companions transfer mass to their white dwarf companions, thereby rapidly building up the critical mass M_{env} that leads to explosion.

The second class of recurrent novae is that typified by U Sco and including V394 CrA and LMC-RN. These are among the fastest novae known; they also obey the M_v(max)–t_2 relationship. Again, some of their eruptions may have been missed because of their brevity. The declining parts of their light curves vary from eruption to eruption. All have orbital periods of about 1 day. Their spectra are dominated by helium lines in the post-nova stage.

The final star, T Pyx, is unique. It rises slowly to maximum, taking about 7 days for the initial rise and a further 20 to 30 days to maximum, followed by a slow decline. Its distance is very uncertain, so it is not known whether it obeys the M_v(max)–t_2 relationship. Photographs show a double shell, perhaps the ejecta from the 1944 and 1966 eruptions. It is suspected that in its quiescent state T Pyx may be steadily burning some of its hydrogen through nuclear reactions in its envelope.

Symbiotic stars

Among the SYMBIOTIC STARS are about a dozen that are classified as symbiotic novae. These are related to the T CrB type of recurrent novae: they probably all have long orbital periods (the known ones are from 200 to 1000 days) and some have had more than one eruption. However, the rise to maximum is very slow, in the range of 2 months to 16 years, and the duration of eruption is very long—from years to greater than a century. It is currently thought that the eruptions of symbiotic novae are the result of thermonuclear runaways on white dwarf primaries of lower mass than in the T CrB type.

Novae at minimum light

During the long intervals between eruptions, and after they have fully recovered from their latest eruptions, novae spend at least part of their time as non-outbursting, relatively inconspicuous stellar objects. A good example is DQ Herculis, which had not drawn attention to itself prior to its 1934 eruption, and which remained relatively unstudied in its post-novae state for 20 years before M F Walker discovered it to be an eclipsing binary with an orbital period of 4 h 39 min. This was the first cataclysmic variable star to be recognized as a short-period binary, though UX UMa and AE Aqr were previously known as spectroscopic binaries, but only retrospectively classified as nova-like variables.

Most novae eventually return to their pre-nova brightness (as found on archival photographic plates) and become indistinguishable from nova-like variables. For the brightest novae (table 1) the quiescent magnitude is quite bright. This implies that the currently known nova-likes probably include novae that erupted unnoticed in past centuries—and also that some of the nova-likes are 'pre-novae', in the sense that they will become novae in the future.

As mentioned earlier, some novae pass through a stage as dwarf novae during their post-nova decline. A few novae (Nova Her 1960, Nova Sgr 1919 and recurrent Nova Sgr 1962) showed dwarf nova outbursts prior to eruption; the first two of these started outbursts again in their post-nova phases.

There is evidence that at least some novae fade to very faint magnitudes (implying a large reduction in mass transfer from their secondary stars) centuries after their eruptions. Nova Vul 1670 (table 1) is an example, but more significant is that none of the naked eye novae recorded in Eastern records (and which would be expected to have post-nova apparent magnitudes in the range 10–14) have been recovered in modern surveys for nova-likes. The reason for the low state may be because heating of the secondary star by radiation from the hot post-nova white dwarf causes excessive mass transfer, and the secondary later adjusts to a slightly

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

smaller radius, reducing mass transfer for many centuries, which maintains the long-term average rate of transfer determined by orbital evolution.

From the existence of the M_v(max)–t_2 relationship described above, and if nova remnants all had the same absolute brightness M_v(min) at minimum, it would be expected that the *range* $\Delta M_v = M_v$(min)-M_v(max) would be well correlated with rate of decline, t_2. (Note that the range in apparent magnitude $\Delta m_v = m_v$(min)—m_v(max) $= \Delta M_v$, and this is independent of interstellar extinction, since the extinction is applicable to both m_v(min) and m_v(max).) This is indeed the case, but there is a large spread in the relationship, which results from the dominance of the accretion disc at minimum light. At maximum of eruption, a nova would look approximately the same brightness independent of the direction from which it is observed. The minimum brightness, however, depends very strongly on the inclination of the binary orbit: if the system is seen at low inclination, i.e. the disc is seen nearly face-on, it is relatively bright. Seen at high inclination, however, the disc is edge-on and quite faint. The result is an unusually large Δm_v for eclipsing systems like DQ Herculis. The average M_v(min) for novae in quiescence is about +4, but the range is $2 \lesssim M_v(\text{min}) \lesssim 9$, correlated with orbital inclination.

Rare exceptions to this range of minimum magnitude can occur if the white dwarf primary has a strong magnetic field, preventing the formation of an accretion disc. An example is V1500 Cyg, which erupted from a minimum magnitude fainter than 21st (the magnitude listed in table 1 is the post-eruption outburst, probably representing a much higher rate of mass transfer than before eruption).

Cataclysmic Variables: the Magnetic Systems

Cataclysmic variables (CVs) are CLOSE BINARY STARS in which the most massive component is a WHITE DWARF (WD) and the companion is usually a more normal star—commonly a main sequence star but occasionally a giant. The majority of CVs steadily transfer mass from the companion to the WD through an ACCRETION DISK surrounding the WD, but, just as about 5% of isolated WDs have detectable magnetic fields, so do about 25% of the WDs that occur in CVs. If the magnetic field is strong (greater than about 10 MG = 10×10^6 G) it prevents the formation of an accretion disk, and the result is that the gas leaving the companion is magnetically channeled direct to the surface of the WD. The WD itself rotates on its axis at the same rate as the revolution of the binary—it is locked to the secondary by the interaction of their magnetic fields. The prototype of this kind of object is AM HERCULIS, leading to the description of this class as AM Her stars, or (as the infalling gas radiates its energy in the strong magnetic field of the WD and this radiation is therefore cyclotron emission, which is strongly polarized), as polars. The strongest field so far measured in a polar is 230 MG in AR UMa; AM Her itself has one of the lowest fields found in a polar, 14 MG.

If the WD has a weaker magnetic field (less than a few million gauss) its interaction with the (intrinsic or induced) field of the companion is insufficient to force co-rotation, with the result that the WD has a different, usually much shorter, rotation period than the binary period. Furthermore, the field can only prevent formation of a disk quite close to the WD, with the result that an accretion disk does form, but the central part is missing—where the energy density in the field is greater than that of the kinetic inflow of gas and can therefore determine the accretion flow. The prototype of this kind of object is DQ HERCULIS. The group as a whole is usually known as intermediate polars (IPs) (being intermediate between strongly magnetic and non-magnetic), with DQ Her stars preferably kept as a description of the subset of most rapidly rotating WD primaries (e.g. DQ Her itself with 71 s rotation period)—although some authors use DQ Her stars as the general type. The majority of IPs have primaries rotating with periods of tens of minutes. Polarized radiation, modulated at the spin period of the WD, has been detected in only three IPs, presumably those with the strongest fields. Because of the large amount of unpolarized radiation from the (truncated) accretion disk, polarized radiation in IPs is very much diluted; furthermore, the weaker fields result in the cyclotron emission peaking in the infrared, where it is more difficult to detect.

The process of accreting matter onto the WD also transfers angular momentum. However, the result is not straightforward—not only is there a material torque on the WD, due to direct (but non-radial) impact of the gas, there are also torques resulting from the interaction of the magnetic field lines connecting the WD with the accretion disk, part of which is rotating faster than the WD and part is rotating slower. These torques can balance, with the result that the WD rotation period reaches an equilibrium state. However, in general the rotation rates are found to be increasing in some and decreasing in others—at typically only a few seconds per century—as they seek the equilibrium.

The magnetic field strengths in isolated WDs extend down to the current limit of detection—about 50 000 G, so it is to be expected that the same would be true of the WDs in CVs. Such fields are too weak to detect directly in CVs (i.e. by the ZEEMAN EFFECT or by the presence of polarization), but there is indirect evidence of the presence of such weak fields in some CVs through the appearance of dwarf nova oscillations (DNOs) during the outburst of some dwarf novae (also known as U GEM STARS) and intermittently in some nova-like variables (which are rather like dwarf novae stuck permanently in outburst). The DNOs are periodic brightness variations with periods typically in the range 5–40 s and are currently interpreted as magnetic channeling of accreting gas in the very inner region of the accretion disk, just above the surface of the WD. One difference from the IPs is that, whereas IPs have very stable brightness modulations, the DNOs vary rapidly in period—sometimes changing by a factor of 2 within a day. An explanation for this is that the intrinsic fields of the WDs are too small to prevent the accreting gas from slipping around the equator. Whereas in polars and IPs the accreting gas is coupled to the whole body of the WD, in the DNOs we see the effect of an equatorial belt spinning up in response to accreted angular momentum, carrying its (probably self-generated) magnetic field around with it. The existence of long-lived rapidly spinning equatorial belts after dwarf nova outbursts has recently been established through spectra obtained with the HUBBLE SPACE TELESCOPE. Not all dwarf novae or nova-like variables show DNOs, presumably because there are some CVs that have magnetic fields too small to effect any magnetic channeling at all of the accretion flow—in such cases the accretion disk would reach down to the surface of the WD. This may happen also in those dwarf novae where DNOs are seen to cease near the maximum of outburst; at such times the accretion flow is probably crushing the magnetosphere of the WD down to the WD surface.

In all of the classes of magnetic CV, modulated x-ray and EUV emission is seen—at the orbital period in polars, at the WD rotation period in IPs and at the DNO period in outbursts of dwarf novae. Such energetic radiation is emitted from the strongly shock-heated region as the channeled accretion flow impacts the surface of the WD, producing a very high x-ray luminosity (indeed, many of the polars and IPs were first discovered during x-ray surveys of the sky). Some of the radiation leaving such heated spots on the surface of the WD may intercept the surface of the truncated accretion disks in IPs and

Dirac House, Temple Back, Bristol, BS21 6BE, UK

weakly magnetic CVs. In effect, a rotating beam sweeps across the surface of the disk—and also the side of the companion star pointing towards the WD. This radiation is partly processed (degraded) into the optical region of the spectrum, enabling us to detect indirectly the rotating beam. Two optical modulations with different periods can be produced—one through reprocessing from the disk and one from reprocessing on the companion star. In successive sweeps the companion has moved round a little in its orbit, so the signal from the companion has a longer period (this is like the difference between SIDEREAL PERIOD and SYNODIC PERIOD for planets), and this sometimes is the only optical period detectable. In the x-ray region we see the direct beam from the WD. As a result, in some IPs the period (sidereal) of the x-rays and the period (synodic) in the optical differ (their difference in frequency is exactly equal to the orbital frequency—which is how this model for IPs was established in the first instance).

In DQ Her and some outbursting dwarf novae and nova-like variables, observations of the changes in the rapid brightness modulations during eclipse by the companion star show phase changes which again point to a rotating beam emitted from the WD (see DQ HERCULIS).

The accumulation of hydrogen-rich material from the companion onto the surface of a WD leads eventually to a nova explosion (see NOVAE). The magnetic systems are no exception: Nova Cygni 1975 (also known as V1500 Cyg), one of the fastest and brightest novae of the 20th century, was found after it had settled back to its quiescent state to be a polar—or almost so. Its orbital period (determined spectroscopically and photometrically) is 0.139 612 9 d and its WD rotation period (determined from the period of the polarization modulation) is 0.137 154 d. The slight difference was caused by the effects of the nova explosion in 1975, during which the outer layers that were ejected from the WD exchanged some mass and angular momentum with the companion. The rotation period of the WD in V1500 Cyg is observed to be changing at such a rate that synchrony with the orbital period will be regained after about 180 yr. Three other desynchronized polars are known, which must have been undetected novae in recent centuries. There are two IPs among the known novae (Nova Persei 1901 and Nova Puppis 1963).

Celestial Coordinates

Celestial coordinates are the means of specifying the location of a celestial object within some reference frame. In astronomy, it is necessary and convenient to represent the position of an object, such as a star or a planet, in several different coordinate systems according to the context in which the position is to be used. Coordinates of an object correspond to a particular way of expressing the position of a point with respect to a coordinate frame, such as a set of rectangular axes. In general, each position is represented by a set of three coordinates. In many cases, the distance of the object is not known, so two coordinates are sufficient to represent the direction to the object, although three direction cosines may be used. With the availability of more distance estimates in astronomy, the use of three space coordinates is becoming more common.

Many different coordinate systems are used to specify the positions of celestial objects. Each system depends on the choice of coordinate frame and on the way of specifying coordinates with respect to the frame. The term celestial coordinate frame is used here for a coordinate frame that does not rotate with the Earth (or other planet), so that the coordinates of stars, for example, change only slowly with time (see CELESTIAL COORDINATE SYSTEMS).

In general, an object is moving with respect to the coordinate frame, and the coordinate frame is moving and rotating in 'space'. Therefore, it is necessary to specify the time to which the three spatial coordinates refer and the time for which the coordinate frame is defined. These two times may be the same, but are often different. Also, positions may be of several kinds, according to whether or not allowances have been made for aberration, diurnal rotation, refraction and other factors that affect the direction in which an object is observed. These are referred to as mean, true and apparent places. EPHEMERIDES and catalogs that represent high-precision positions and properties of astronomical objects at given times must always be accompanied by a precise statement that specifies all of these various factors, if the numbers are to be used properly to their full precision.

The vector $\boldsymbol{r}$ from an origin to the object may be represented by rectangular coordinates (x, y, z); that is, by the projections of the distance $\boldsymbol{r}$ on the three axes. It can also be represented by spherical coordinates, in which direction is usually specified by the longitudinal angle (λ) in the x–y-reference plane and the latitudinal angle (β) from the reference plane. Less frequently the polar angle ($90^\circ - \beta$), or complement of the latitudinal angle, is used. The longitudinal and latitudinal angles are given different names and symbols in different coordinate frames.

The geometric transformations of positions between different coordinate systems, and the allowances for physical effects, may be carried out using the techniques of spherical trigonometry or those of vector and matrix algebra. The concept of the celestial sphere may be used for purposes of explanation, with the arcs on the sphere representing angles between directions. The center of the sphere can be located in many different places, but in most cases the sphere will be used to illustrate a particular reference frame with a specific origin. It must be remembered that when an object represented on the sphere is changing radial distances from the center along with transverse motion, these changes must be incorporated into the mathematics of the computation.

The designations used to indicate the principal origins of celestial coordinate frames are as follows.

(1) Topocentric: viewed or measured from the place of observation on the surface of the Earth.
(2) Geocentric: viewed or measured from the center of the Earth.
(3) Selenocentric: viewed or measured from the center of the Moon.
(4) Planetocentric: viewed or measured from the center of a planet (with corresponding designations for individual planets).
(5) Heliocentric: viewed or measured from the center of the Sun.
(6) Barycentric: viewed or measured from the center of the mass of the solar system.

The principal celestial reference planes through the appropriate origins are as follows.

(1) Horizon: the plane that is normal to the local vertical (or apparent direction of gravity) and passes through the observer.
(2) Local meridian: the plane that contains the local vertical and the direction of the axis of rotation of the Earth.
(3) Celestial equator: the plane that is normal to the axis of rotation of the Earth and passes through the Earth's center.
(4) Ecliptic: the mean plane (i.e. ignoring periodic perturbations) of the orbit of the Earth around the Sun.
(5) Planet's meridian: a plane that contains the axis of rotation of the planet and passes through a surface feature.
(6) Planet's equator: the plane that is normal to the axis of rotation of the planet and passes through the planet's center.
(7) Orbital plane: the plane of the orbit of a body around another (e.g. of a planet around the Sun or barycenter).
(8) Invariable plane or Laplacian plane: the plane that is normal to the axis of angular momentum of a system and passes through its center.
(9) Galactic equator: the plane through the central line of the local Galaxy (Milky Way).

The line of intersection of the mean plane of the celestial equator and the ecliptic defines the direction of the equinox (Υ). Using the projection of this direction as the origin, the right ascension (α) is measured in the plane of the equator and celestial (or ecliptic) longitude (λ) is

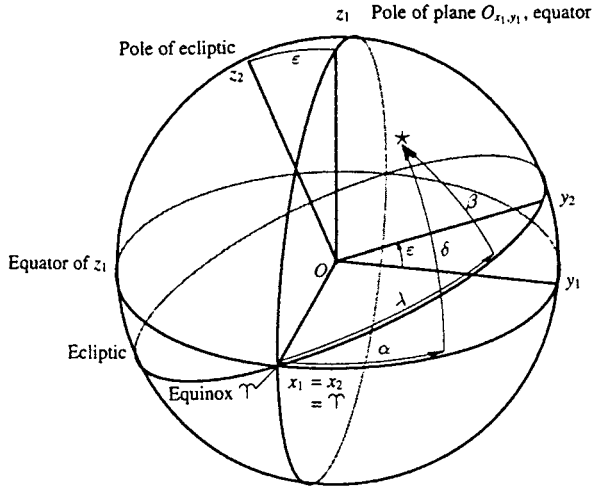

Figure 1. Equatorial and ecliptic reference planes.

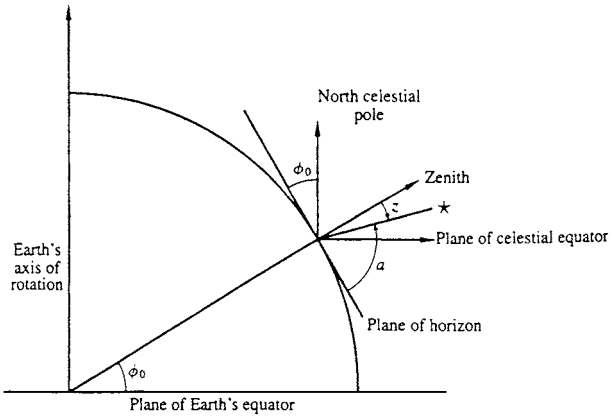

Figure 2. Topocentric coordinates.

measured in the plane of the ecliptic (see figure 1). Right ascension is usually expressed in time measure from 0 h to 24 h, and both right ascension and longitude are measured in the positive (or right-handed) sense. The complement of right ascension with respect to 24 h is known as sidereal hour angle (SHA); in navigational publications it is usually expressed in degrees. Declination is measured from the equatorial plane, positive to the north, from 0° to 90°. Celestial latitude is measured from the ecliptic plane, positive to the north, from 0° to 90°.

The equinox is at the ascending node of the ecliptic on the equator; this is the direction at which the Sun, in its annual apparent path around the Earth, crosses the equator from south to north. It is also referred to as 'the first point of Aries', and it is the vernal (spring) equinox for the northern hemisphere (see figure 1). The inclination of the plane of the ecliptic to the plane of the equator is known as the OBLIQUITY OF THE ECLIPTIC (ε).

The equator and ecliptic are moving because of the effects of perturbing forces on the rotation and motion of the Earth. Hence, the equinox and obliquity change as a function of time, so these celestial coordinate frames must be carefully defined in such a way that they can be related to a standard frame that may be regarded as being fixed in space.

The lines of intersection of the plane of the meridian with the planes of the horizon and equator define the directions from which AZIMUTH (A) and local HOUR ANGLE (h) are measured. Azimuth is measured in the plane of the horizon from the north, increasing in positive value toward the east. Local hour angle is measured in units of time: 1 h for each 15°, positive to the west with respect to the local meridian.

The latitudinal angles with respect to the horizon and equator are known as ALTITUDE (a) and DECLINATION (δ). Altitude is measured positively toward the zenith; in astronomy the zenith distance, angle from local vertical ($z = 90° - a$), is more generally used. Declination (δ) is, measured from the equator, positive toward the north pole of rotation. The ZENITH DISTANCE of the north pole, which is the same as the codeclination of the local vertical (or zenith), is equal to the geographic colatitude of the point of observation.

There are two main topocentric coordinate frames. One is based on the direction of the local vertical, which defines the plane of the horizon; the other is based on the direction of the Earth's axis of rotation, which defines the plane of the celestial equator. The local meridian, which contains the direction of the local vertical and the direction of the axis of rotation, is common to both frames.

The angular coordinates in the topocentric coordinate frame of the horizon and local meridian are known as azimuth and altitude. Azimuth (A) is measured from 0° to 360° from north in the direction of east; that is, in the negative sense with respect to the direction of the zenith. (In some circumstances azimuth may be measured from the south, and so the convention that is used should be stated to avoid ambiguity.) Altitude (a) is measured positively from the horizon toward the zenith. Both the altitude and the azimuth of any celestial object change rapidly as the Earth rotates and therefore for many purposes it is more convenient to use the topocentric frame of the celestial equator and the local meridian. The direction of the north celestial pole is parallel to the Earth's axis of rotation, and the altitude of the pole is equal to the geographic latitude of the point of observation. This is illustrated in figure 2, which shows the Earth as a sphere.

In this topocentric equatorial frame, the angular coordinates are known as local hour angle (LHA, or h) and declination (δ). LHA is measured from 0° to 360°, or from 0 h to 24 h, from south in the direction of west (i.e. in the negative sense with respect to the direction of the north celestial pole), and the LHA of a celestial object increases by about 15°, or 1 h, for every hour of time. Declination is measured from the equator to the celestial pole, positive toward the north. The declination of a celestial object is not changed by the diurnal rotation of the Earth.

Celestial Equator

The great circle on the celestial sphere obtained by the intersection with the sphere of the plane of the Earth's equator. When the Sun lies in plane, day and night are everywhere of equal length. Known as equinox, this occurs twice each year, when the Sun is at one of the two points at which the celestial equator and the ecliptic intersect.

Celestial Latitude

The angular distance between the ecliptic and a celestial body measured in a direction perpendicular to the ecliptic, and taking values between 0 and 90°. The position of a celestial body may be expressed in terms of celestial latitude (denoted by β) and celestial longitude.

See also: celestial equator, celestial longitude, celestial poles, celestial sphere, ecliptic, equinox.

Celestial Longitude

The angle between the great circle passing through the poles of the ecliptic and the vernal equinox, and the great circle passing through these poles and a celestial object, measured in an anticlockwise (i.e. eastward) direction from the vernal equinox. In other words, it is the angular distance measured along the ecliptic between the vernal equinox and the point on the ecliptic such that the angle between the vernal equinox, this point, and a star is a right angle. Planetary positions are sometimes expressed in terms of celestial longitude (denoted λ) and celestial latitude.

Celestial Mechanics

Celestial mechanics is the study of objects in the universe moving under the influence of a variety of forces. Nowadays the term is generally taken to mean the theory of motion of objects in the solar system, although it can still be applied to the dynamics of stars involved in multiple systems; the gravitational dynamics of stellar clusters and galaxies are usually treated as separate areas of investigation because they make use of different techniques. Celestial mechanics is primarily concerned with the dynamical consequences of the force of gravity between objects but additional forces can operate. These range from the tidal interactions of planets and satellites to the effects of electromagnetic radiation on small particles. Once considered to be a somewhat archaic branch of astronomy, there has been a renewed interest in celestial mechanics in recent years with the realization that its deterministic equations of motion can give rise to chaotic solutions. This has led to numerous applications in the solar system and an improved understanding of long-term dynamical evolution.

Orbital theory

In the 17th century KEPLER derived his three laws of planetary motion empirically based on observations (see KEPLER'S LAWS). Later in the same century NEWTON showed that Kepler's laws were the consequence of a simple inverse square law of force whereby the magnitude of the force of gravitational attraction between two masses, m_1 and m_2, separated by a distance d, is given by

$$F = \mathcal{G}\frac{m_1 m_2}{d^2}$$

where $\mathcal{G} = 6.672 \times 10^{-11}$ m^3 kg^{-1} s^{-2} is the universal gravitational constant. Newton showed that the orbit of one mass with respect to the other would describe a CONIC SECTION (i.e. circle, ellipse, parabola or hyperbola) where values of the position and velocity vectors ($\boldsymbol{r}$ and $\boldsymbol{v}$, respectively) at a particular instant determine the type of path followed. Because the angular momentum of the system is a constant, the relative orbit of the two masses defines a plane—the orbit plane—and so plane polar coordinates fully describe the relative motion. In the case of elliptical orbits the polar equation giving the radial distance, r, as a function of the true longitude, θ, is

$$r = \frac{a(1-e^2)}{1 + e\cos(\theta - \varpi)}$$

where a is the semimajor axis of the ellipse and e is its eccentricity (figure 1). The angle ϖ gives the orientation of the ellipse with respect to a fixed reference line at $\theta = 0$. For the gravitational interaction of two masses the quantities a, e and ϖ are all constant while θ increases non-linearly with time. Elliptical orbits are bounded with r oscillating between between finite limits; consequently they are periodic in nature.

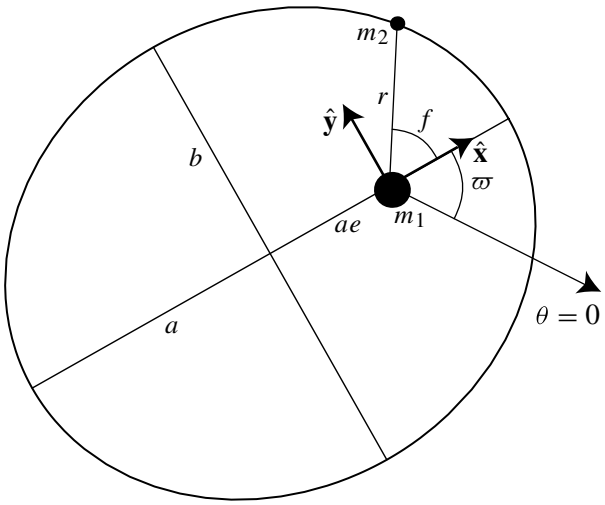

Figure 1. The geometrical properties of planar elliptical motion with semimajor axis a, eccentricity e, semiminor axis $b = a(1-e^2)^{1/2}$ and longitude of pericenter ϖ. The mass m_2 has radial distance r from m_1, true anomaly f, and true longitude $\theta = f + \varpi$. The unit vector in the $\hat{x}$ direction is taken along the major axis of the ellipse directed towards the point of closest approach (the pericenter); the $\hat{y}$ direction is perpendicular to this line in the plane of the orbit. The mass m_1 is at one focus of the ellipse.

The polar equation of the ellipse does not provide a means of calculating the position of an object at a given time. However, this can be done using Kepler's equation which relates the eccentric anomaly, E, to the mean anomaly, M. The components of the position vector with respect to the $\hat{x}$–$\hat{y}$ frame can be written as $r\cos f = a(\cos E - e)$ and $r\sin f = a(1-e^2)^{1/2}\sin E$. Kepler's equation can be written as

$$M = E - e\sin E$$

where E and M are measured in radians. The mean anomaly has the useful property that it increases with time at a fixed rate given by the mean motion, $n = [\mathcal{G}(m_1 + m_2)/a^3]^{1/2}$ with the time needed to complete one orbit (one orbital period) given by $T = 2\pi[a^3/[\mathcal{G}(m_1 + m_2)]]^{1/2}$. Knowing the time at which the mass m_2 is at a particular longitude (usually taken to be the time of pericenter passage, τ) it is possible to calculate the location of the mass m_2 at any subsequent time in the context of the two-body problem. However, because Kepler's equation is transcendental in E it is usually necessary to undertake a numerical solution.

In the case of motion in three dimensions it is necessary to define two additional angles: the orbital inclination, I, and the longitude of ascending node, Ω (figure 2). Furthermore, the argument of pericenter, ω, is used to denote the angle between the ascending node and the pericenter and the longitude of pericenter is now taken to be $\varpi = \omega + \Omega$ where ω and Ω are in different

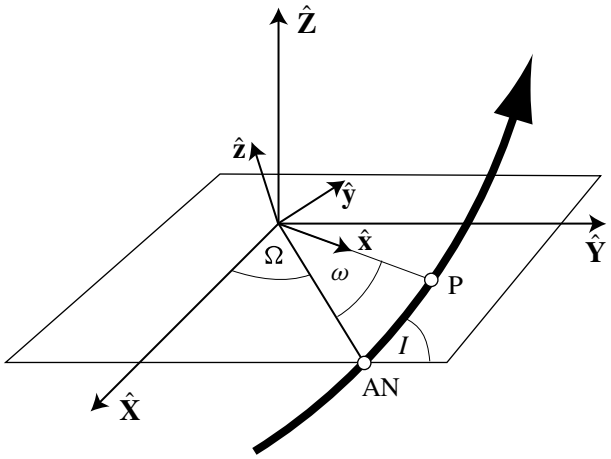

Figure 2. The geometrical properties of three-dimensional elliptical motion along an orbit (thick curve) inclined by an angle I with respect to the $\hat{\boldsymbol{X}}$–$\hat{\boldsymbol{Y}}$ reference plane. The points labeled AN and P denote the ascending node and pericenter, respectively. The ascending node has a longitude Ω with respect to the reference ($\hat{\boldsymbol{X}}$) direction; the pericenter makes an angle ω with respect to the line to the ascending node. The longitude of pericenter is now defined to be $\varpi = \omega + \Omega$.

planes. Note that even though this motion is viewed in a coordinate system inclined relative to the orbital plane, the fundamental properties of the Keplerian orbit remain unchanged.

The motion of two bodies under their mutual Newtonian gravitational attraction (the two-body problem) is one of the few integrable problems in celestial mechanics. It has the property that the orbiting mass returns to the same value of r after f has completed an azimuthal cycle of exactly 2π. The addition of only one more body destroys this symmetry. The problem becomes non-integrable in the sense that no practical mathematical solution is possible although some analytical results can still be derived (see THREE-BODY PROBLEM).

Lunar theory is a branch of celestial mechanics devoted to the study of the Moon's motion. This problem is relatively simple if it is confined to predicting the Moon's path around a spherical Earth. However, the reality is that solar perturbations are also significant and there are more subtle, long-term effects to consider such as modifications to the Earth's spherical shape caused by tides and rotation.

The solar system has a hierarchic structure of several subsystems, each consisting of a central mass with one or more orbiting smaller masses at each level. For example, the planets orbit the Sun but most also have their own small natural satellites. Therefore, when considering the motion of a satellite orbiting close to a planet the perturbations from the Sun can usually be ignored. This does not mean that the orbit is a simple, fixed ellipse; the planet's non-sphericity causes short- and long-term changes in some of the orbital elements. Planetary orbits themselves are not fixed because all planets perturb one another. Therefore, although at any given instant the planet is always following an elliptical path determined by its instantaneous position and velocity (this is referred to as its osculating orbit), the shape and orientation of that ellipse are continually changing owing to perturbations from the other planets. Such changes are small but detectable over time.

In general the smallest objects, such as PLANETARY RING particles and METEOROIDS, are subjected to the widest variety of additional perturbations in the form of non-gravitational forces. Their size means that the effect of incident electromagnetic radiation can affect their orbits. For example, the POYNTING–ROBERTSON EFFECT is caused by the non-isotropic re-emission of radiation and is important for particles whose size is comparable with the wavelength of the radiation. It results in damping of the eccentricity and inclination and a decrease in the semimajor axis regardless of whether the particle is in a heliocentric or planetocentric orbit. This effect is thought to be responsible for the large-scale transport of collisional dust from the asteroid belt through to the inner solar system (see INTERPLANETARY DUST).

In the years following Newton's pioneering work (see CELESTIAL MECHANICS IN THE EIGHTEENTH AND NINETEENTH CENTURIES) considerable effort was devoted to quantifying and then predicting the motions of the objects that make up the solar system. One of the outstanding successes of celestial mechanics was the independent explanations by John Couch ADAMS and LEVERRIER for the observed anomalies in the motion of the outer planets. This led directly to the discovery of the planet Neptune by GALLE in 1847. The improvement in the precision with which planetary orbits could be understood led to an even more momentous discovery in the 20th century. EINSTEIN showed that a small discrepancy of $0.43''$ yr^{-1} in the motion of Mercury's longitude of perihelion was due to the fact that Newton's theory of gravity was incorrect and that his own general theory of relativity could account for the observations (see GENERAL RELATIVITY AND GRAVITATION).

Celestial mechanics gained importance as a practical science with the advent of the space age in the 1960s. The increased number of artificial satellites in Earth orbit meant that the gravitational field of the Earth could be studied in great detail by monitoring satellite orbits and how they changed with time. The need to send spacecraft to other planets led to the use of celestial mechanics in the design of complicated orbital tours (see the GALILEO and CASSINI MISSIONS). The gravity assist technique, whereby a spacecraft changes its orbital energy by means of a close flyby of a planet or satellite, has become the mainstay of the robotic exploration of the outer solar system. Although ground-based observations can be used to estimate the masses of planets and satellites, the careful monitoring of spacecraft trajectories for small deviations has resulted in direct measurements of the gravitational field of many solar system objects.

Gravitational perturbations

Historically perturbation theory in celestial mechanics has been divided into what are called general and special

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

perturbations. General perturbation theory consists of studying the evolution of a perturbed orbit by considering the analytical solution of the differential equations describing the variation of the object's orbital elements or its coordinates. In contrast special perturbation theory consists of analyzing the orbit using a numerical or seminumerical solution of the equations. Although greater insight is gained from an analytical solution, this is frequently impossible in celestial mechanics for all but the simplest of systems. A numerical solution can offer insight into the problem and the availability of fast digital computers allows large numbers of starting conditions to be considered so that some understanding can be achieved.

Consider a central mass m_c and two orbiting masses, m and m', with position vectors $\boldsymbol{r}$ and $\boldsymbol{r}'$ with respect to m_c. The motion of m can be described by the solution to the vector equation

$$\ddot{\boldsymbol{r}} = \boldsymbol{\nabla}(U + \mathcal{R})$$

where

$$U = \mathcal{G}\frac{m_c + m}{r}$$
$$\mathcal{R} = \frac{\mathcal{G}m'}{|\boldsymbol{r}' - \boldsymbol{r}|} - \mathcal{G}m'\frac{\boldsymbol{r}\cdot\boldsymbol{r}'}{r'^3}.$$

Here U represents the potential that gives rise to the two-body Keplerian motion of m around m_c and $\mathcal{R}$ represents the perturbing potential or disturbing function experienced by m due to m'. There are similar expressions for the effect of m on m'. Note that traditionally in celestial mechanics the potential is taken to be a positive quantity. While it is relatively trivial to express $\mathcal{R}$ in terms of Cartesian coordinates, it is more difficult to express it in terms of the orbital elements of m and m'. Nowadays this can easily be accomplished using computer algebra to undertake the necessary series manipulation.

The expansion of $\mathcal{R}$ has the general form

$$\mathcal{R} = \frac{\mathcal{G}m'}{a'}\sum_j S(a, a', e, e', I, I')\cos\varphi$$

where j is an integer and φ is a combination of longitudes (i.e. angles referred to a fixed direction) that can be written as

$$\varphi = j_1\lambda' + j_2\lambda + j_3\varpi' + j_4\varpi + j_5\Omega' + j_6\Omega$$

where the j_i are all integers and $\lambda = M + \varpi = n(t - \tau) + \varpi$ is the mean longitude. Each cosine argument, φ, satisfies the d'Alembert relation whereby $\sum_{i=1}^{6} j_i = 0$. Another important property is that the absolute value of the coefficient of ϖ', ϖ, Ω' and Ω (i.e. $|j_3|$, $|j_4|$, $|j_5|$ and $|j_6|$) is equal to the lowest power of e', e, $s' = \sin\frac{1}{2}I'$ and $s = \sin\frac{1}{2}I$, respectively, that occurs in the accompanying term. All the arguments can be classified according to the absolute value of the sum of the coefficients of the mean longitudes, λ' and λ in the cosine argument. Therefore an expansion that includes Nth-order arguments will involve Nth-order powers of the eccentricities and inclinations.

The disturbing function is used in conjunction with LAGRANGE's equations to give equations for the variations of the orbital elements. To lowest order in e and I these can be written as

$$\frac{\mathrm{d}a}{\mathrm{d}t} = \frac{2}{na}\frac{\partial\langle\mathcal{R}\rangle}{\partial\lambda}$$
$$\frac{\mathrm{d}e}{\mathrm{d}t} = -\frac{1}{na^2e}\frac{\partial\langle\mathcal{R}\rangle}{\partial\varpi}$$
$$\frac{\mathrm{d}\varpi}{\mathrm{d}t} = +\frac{1}{na^2e}\frac{\partial\langle\mathcal{R}\rangle}{\partial e}$$
$$\frac{\mathrm{d}I}{\mathrm{d}t} = -\frac{1}{na^2\sin I}\frac{\partial\langle\mathcal{R}\rangle}{\partial\Omega}$$
$$\frac{\mathrm{d}\Omega}{\mathrm{d}t} = +\frac{1}{na^2\sin I}\frac{\partial\langle\mathcal{R}\rangle}{\partial I}$$

where $\langle\mathcal{R}\rangle$ contains the required terms in the disturbing function expansion for an external perturber.

To use Lagrange's equations in some applications in celestial mechanics involves the identification of those terms in the expansion of $\mathcal{R}$ that are likely to be important for the particular problem of interest with the assumption that all the non-important, short-period terms will have zero time-averaged effect. The key orbital elements in this process are the semimajor axes, a and a'.

In the unperturbed problem the mean longitudes, λ' and λ, increase linearly at rates n' and n, respectively, whereas all the other angles in a general argument φ are constant. In the perturbed system λ' and λ are still rapidly varying quantities, but the other angles are slowly varying. Therefore, any arguments which do not involve mean longitudes are slowly varying. These give rise to long-period or secular terms. Under certain assumptions it is possible to derive a secular theory for planetary orbits. The resulting coupled equations of motion can be solved analytically to give approximate orbital elements (except mean longitudes) as a function of time.

Consider a general argument, $\varphi = j_1\lambda' + j_2\lambda$ where a and a' are such that $j_1n' + j_2n \approx 0$ and φ varies with a period longer than either of the two orbital periods. This occurs when there is a simple numerical relationship between the two mean motions or orbital periods. These arguments give rise to resonant terms in the expansion (see RESONANCE). In terms of the semimajor axes the equivalent condition is $a \approx (|j_1|/|j_2|)^{2/3}a'$. The solar system contains more pairs of objects in resonance than would be expected to occur by chance. This is probably due to the effects of tidal torques (see TIDES) causing satellite orbits to expand at differing rates over the age of the solar system.

Resonant terms are localized in semimajor axes. While a particular combination of angles may be slowly varying at one semimajor axis of the perturbed body, the same combination could be varying rapidly at another. In contrast the secular terms can be considered as global. Any argument which is neither secular nor resonant is considered to give rise to a short-period term.

Natural satellites such as the Moon raise tides on their parent planets; the planet itself may also be rotationally

distorted. In each case it is possible to derive an equivalent disturbing function to represent the potential experienced by the orbiting mass and apply Lagrange's equations. For example, it can be shown that an elliptical orbit of semimajor axis a about an oblate planet of radius R_p would precess at a rate $\dot{\varpi} \approx \frac{3}{2} n J_2 (R_p/a)^2$ where n is the mean motion and J_2 is the second zonal harmonic coefficient of the planet.

One of the major theoretical advances in celestial mechanics in recent years has been the derivation of algebraic mappings to allow perturbed orbits to be followed numerically for extended periods. These mappings (or maps) can be classified into three broad types:

- resonance maps, where the disturbing function at a particular resonant location is derived—the secular part is integrable and the resonant part can be replaced by a sequence of Dirac δ-functions applied as impulses;
- encounter maps, where the orbit is considered as simple Keplerian motion until a conjunction or close approach to the perturbing body takes place—the perturbation is applied as an impulse.
- N-body maps, where the Cartesian equations of motion are re-formulated in a special coordinate system that isolates the two-body Keplerian part from the interaction part—use is made of Dirac δ-functions to treat the interaction part as impulses.

It has now become commonplace to use N-body maps to carry out numerical investigations of long-term stability in the solar system.

Chaotic motion

The fact that motion in the solar system arises from a simple mathematical law led to the belief that discovering the laws that governed the universe was equivalent to being able to predict its past and future state. This opinion was exemplified by LAPLACE's view of the universe as an entirely deterministic system. However, at the end of the 19th century POINCARÉ's study of the three-body problem gave the first indication that deterministic systems could admit unpredictable solutions.

In the solar system chaos has been invoked to explain such diverse phenomena as the KIRKWOOD GAPS in the asteroid belt and the unusual rotation of the Saturnian satellite HYPERION. It is now recognized that chaos has played an important role in shaping the dynamical structure of the solar system.

One of the key problems of celestial mechanics is the stability of the solar system. Modern numerical simulations show that the planetary orbits, especially those of the inner planets, are technically chaotic in the sense that an error as small as 0.01 m in a planet's position today propagates exponentially and it becomes impossible to predict its location in $\sim 10^7$–10^8 yr. Nevertheless, the orbits remain close to their current configurations over timescales comparable with the age of the solar system. The one exception is Mercury where some studies have revealed genuine orbital instability ($e \rightarrow 1$) in $\sim 10^{10}$ yr. The exact mechanism that gives rise to such chaotic behavior is still unknown although secular interactions between planets are thought to be responsible. With the discovery of other planetary systems it is clear that our understanding of these processes can be tested in order to discover which distributions of planetary masses and orbits give rise to configurations that are stable over the lifetime of a star.

Celestial Mechanics in the Eighteenth and Nineteenth Centuries

CELESTIAL MECHANICS (so named by Laplace in 1798) before the twentieth century consisted in the application to the solar system of Isaac NEWTON's law of universal gravitation. By this law, a single body orbiting about a larger body moves in a conic section; the presence of a third body perturbs the motion. Celestial mechanics is concerned with the perturbations thus produced.

Newton's treatment of this problem was fundamentally qualitative. In an approximative formulation, he showed that all the known inequalities of the Moon followed qualitatively from the law of gravitation. In his *Theory of the Moon's Motion* (1702), and in the second edition of the *Principia* (Scholium to Proposition III.25), he quantified his theory by fitting it to observations, and adding several quantitative terms without explaining their derivation.

The THREE-BODY PROBLEM was re-formulated in the 1740s as a set of differential equations. This formulation could be rigorous, containing implicitly all the inequalities implied by universal gravitation. (A solution, it turned out, could be pursued only by successive approximations.) That such a formulation was not achieved earlier is attributable to the lack, among mathematicians within the Leibnizian tradition, of a worked-out calculus of trigonometric functions. It was LEONHARD EULER (1707–83) in 1739 who first gave systematic algorithmic rules for the differentiation and integration of trigonometric functions. By 1744 Euler had derived inequalities of the Moon by solving differential equations, but only his results were published.

In 1746 the Paris Academy of Sciences announced as its prize problem for the year 1748 the formulation of a 'theory of Jupiter and Saturn explicating the inequalities that these planets appear to cause in each other's motions'. The prize-winning essay was Euler's; published in 1749, it provided the first generally accessible account of an analytic resolution of the three-body problem. Meanwhile, from 1746, two members of the Paris Academy's prize commission, ALEXIS-CLAUDE CLAIRAUT (1713–65) and JEAN LE ROND D'ALEMBERT (1717–83), separately set about resolving the problem, and therewith deriving the inequalities of the Moon. Clairaut's lunar theory was published in 1752, d'Alembert's in 1754.

Euler and Clairaut on the equations of motion

Euler wrote equations in polar coordinates for Saturn's motion, with the plane of Jupiter's orbit as the r, ϕ plane

$$\mathrm{d}^2r - r\,\mathrm{d}\phi^2 = -\frac{P\,\mathrm{d}t^2}{2} \tag{E.1}$$

$$2\mathrm{d}r\,\mathrm{d}\phi + r\,\mathrm{d}^2\phi = -\frac{Q\,\mathrm{d}t^2}{2} \tag{E.2}$$

$$\mathrm{d}^2z = -\frac{R\,\mathrm{d}t^2}{2}. \tag{E.3}$$

Here P, Q and R are accelerative forces tending to diminish r, ϕ and z; the factor 1/2 arises from Euler's choice of the unit of acceleration.

Clairaut wrote equations similar to (E.1) and (E.2) for r and ϕ, assuming initially the perturbed body's motion to be confined to a plane

$$r\,\mathrm{d}\phi^2 - \mathrm{d}^2r = \left(\frac{M}{r^2} + P\right)\mathrm{d}t^2 \tag{C.1}$$

$$r\,\mathrm{d}^2\phi + 2\mathrm{d}r\,\mathrm{d}\phi = Q\,\mathrm{d}t^2. \tag{C.2}$$

Here M is the sum of the masses of the central and perturbed body, P is the added radial acceleration from perturbation and Q is the transverse acceleration.

To resolve (E.1) and (E.2), Euler replaced $\mathrm{d}t^2/2$ by $a'^3(\mathrm{d}M')^2$, where a' is Jupiter's mean solar distance and M' its mean motion, and substituted for P and Q the accelerative forces involved when Saturn's motion was referred to an immobile Sun. He then took up successively three different approximative assumptions, in which Jupiter's orbit and Saturn's unperturbed orbit were taken either as circles, or one as a circle and the other as an ellipse. Under each hypothesis, he transformed (E.1) and (E.2) into differential equations for the small departures of r and ϕ from their unperturbed values. (Here trigonometric series were necessary; see the next section.) The equations were resolved by the method of undetermined coefficients.

Clairaut obtained an expression for $\mathrm{d}t$ in terms of r and ϕ by integrating (C.2) twice, and with this eliminated t from (C.1). A double integration of the transformed (C.1) then gave him

$$\frac{f^2}{Mr} = 1 - g\sin\phi - c\cos\phi + \sin\phi\int\Omega\cos\phi\,\mathrm{d}\phi - \cos\phi\int\Omega\sin\phi\,\mathrm{d}\phi \tag{C.3}$$

where f, g, c are constants of integration and

$$\Omega = \frac{(Pr^2/M) + (Qr/M)(\mathrm{d}r/\mathrm{d}\phi) - 2\rho}{1 + 2\rho}$$

ρ being

$$\frac{1}{f^2}\int Qr^3\,\mathrm{d}\phi.$$

To evaluate the integrals in (C.3), it was necessary to replace r in Ω by an approximate function of ϕ; Clairaut used

$$\frac{k}{r} = 1 - e\cos m\phi \tag{C.4}$$

the equation of a precessing ellipse, in which k, e, m are undetermined constants.

The introduction of trigonometric series

The lunar and planetary versions of the three-body problem differ because v, the distance between the perturbing and perturbed bodies, is in the lunar case subject only to small variations, expressible by a few terms of a Taylor series, whereas in the planetary case it varies hugely. In the differential equations v occurs as v^{-3}, which fluctuates yet more wildly. What is needed is an expression for v^{-3} permitting formal integration.

Euler resolved this problem by inventing trigonometric series. To a first approximation, he showed

$$v^{-3} = (a^2 + a'^2)^{-3/2}(A + B\cos\theta + C\cos 2\theta + D\cos 3\theta + \cdots) \tag{E.4}$$

where a, a' are the mean solar distances of Saturn and Jupiter, and θ is the heliocentric angle between the two radius vectors; the coefficients C, D, E, etc, are functions of A and B, while A and B are computable by numerical integration. An improved approximation required taking orbital eccentricities into account, and computing coefficients in the series for v^{-5}, v^{-7}, etc. Euler carried the approximation to the order of the first power of the eccentricities.

In 1767 JOSEPH LOUIS LAGRANGE (1736–1813) introduced an efficient new method for determining the series coefficients on the basis of DeMoivre's theorem. Later theorists carried the approximations to higher powers of the eccentricities.

The method of variation of orbital elements

Euler in treating the perturbed planet's motion in the z-direction replaced (E.3) by two first-order equations, one for the orbital inclination and the other for the longitude of the ascending node. In unperturbed motion these quantities are constant; perturbation makes them variable. Euler's approximate expressions for their variations under perturbation showed the inclination subject only to minor oscillations, while the node retrogressed on the orbital plane of the perturbing planet. This was the first analytic determination of the variation of an ORBITAL ELEMENT.

Euler derived the variations of other orbital parameters in later memoirs, but it was Lagrange who chiefly developed the method. In an essay of 1766 Lagrange showed that the ordinary way of computing perturbations by successive approximations inevitably produces terms proportional to the time, as well as nth-order terms in the $(n+1)$th-order approximation. The method of varying orbital parameters avoids this difficulty. In his further work on planetary perturbations, Lagrange used this method exclusively.

The motion of the Moon's apse

Newton published no derivation of the Moon's apsidal motion. In the *Principia's* first edition he cited results of an attempted derivation; its method, we now know, was flawed. In later editions he deleted all reference to it.

The first analytical derivations by Euler, Clairaut and d'Alembert in the 1740s yielded only about half the observed apsidal motion. Clairaut in November 1747 proposed that the inverse-square law be augmented by an inverse-fourth-power term, whence the remaining apsidal motion could be obtained. Then in May 1749 he retracted the proposal. He had discovered that, if he proceeded to the second-order approximation with respect to the perturbing forces (that is, substituting the terms found in the first approximation, with undetermined coefficients, back into the differential equations, and solving again), he obtained nearly the entire observed apsidal motion. No doubt he had expected the second-order approximation to yield only minor modification of the first-order result, and was surprised that two small terms proportional to the transverse perturbing force could produce so large a difference. Euler, by his own very different route, confirmed Clairaut's result. 'Only since this discovery', he wrote to Clairaut, 'can one regard the inverse-square law of attraction as solidly established...'.

Secular variations, real and supposed, to 1785

Secular variations are usually understood as monotonic changes tending to alter an orbital element unidirectionally. EDMOND HALLEY in the 1690s had detected a secular acceleration in the Moon's mean motion since ancient times; later investigators confirmed it. Halley also assigned a secular acceleration to Jupiter and a secular deceleration to Saturn, to accommodate ancient and modern observations (*Tabulae astronomicae*, 1749). Such secular changes, continued indefinitely, would lead to dissolution of the Earth–Moon and planetary systems.

The first major memoir of PIERRE-SIMON LAPLACE (1749–1827), completed in 1773, demonstrated that, to the order of the squares of the eccentricities, the mean motions of the planets are immune to secular variation from planetary perturbation. To the order mentioned, the coefficient of the term proportional to t^2 in the expression of the longitude was identically zero. The apparent secular changes in Jupiter's and Saturn's rates of mean motion, Laplace conjectured, might be due to cometary perturbation.

In a memoir sent to the Paris Academy in October 1774, Lagrange derived differential equations for those perturbations in the orbital inclinations and nodes of the planets that depend on the orientations and sizes of the orbits, but not on where the planets are in them. To do this, he replaced the tangent of the orbital inclination (θ) and the longitude of the ascending node (ω) by new variables, $u = \theta\sin\omega$, $s = \theta\cos\omega$. The resulting differential equations were linear and of the first order, and had a solution of the form

$$\begin{aligned} s_1 &= A_1\sin(at+\alpha) + B_1\sin(bt+\beta) + C_1\sin(ct+\gamma) + \cdots \\ u_1 &= A_1\cos(at+\alpha) + B_1\cos(bt+\beta) + C_1\cos(ct+\gamma) + \cdots \\ s_2 &= A_2\sin(at+\alpha) + B_2\sin(bt+\beta) + C_2\sin(ct+\gamma) + \cdots \\ &\text{etc.} \end{aligned} \tag{G.1}$$

Here the constants $a, b, c, \ldots$ are the roots of an nth-degree equation, and the remaining constants are determinable

from the empirical values of s_1, u_1, s_2, etc, at a given epoch. Lagrange did not solve the entire system (G.1) for all six known planets—an enormous task—but by treating the two large ones, Jupiter and Saturn, as a system apart, obtained four simpler equations. Their solution showed that the nodes and orbital inclinations of these planets oscillated between fixed limits with a period of 51 150 years. Lagrange called these variations secular: they were periodic, to be sure, but their periods were orders of magnitude longer than the periods of ordinary periodic variations, which depend on the positions of the planets in their orbits.

Laplace read Lagrange's memoir of October 1774 on its arrival in Paris, and saw at once (as had Lagrange) that a similar procedure would apply to the eccentricities and aphelia. Thus, introducing the new variables $h = e \sin L$, $k = e \cos L$, where e is the eccentricity and L the longitude of the aphelion, he derived linear, first-order differential equations for $\mathrm{d}h/\mathrm{d}t$ and $\mathrm{d}k/\mathrm{d}t$. The solution was similar in form to (G.1). This analysis was published in 1775.

Laplace now abandoned the problem of planetary perturbations for a decade. The masses of Mercury, Venus and Mars were unknown, and he was uncertain as to the extent of cometary influence on planets.

Lagrange forged ahead. In 1776 he presented a new demonstration of the immunity of the mean motions to secular variation; it contained a classic formulation of the variation of orbital elements, and introduced 'the perturbing function', a potential function from which the perturbative forces in different directions could be derived by partial differentiation. In 1777 he used the perturbing function in the first systematic derivation of all the known integrals of motion for n bodies attracting each other according to the inverse-square law. In 1781 and 1782 he completed the two parts of a major treatise deriving the secular inequalities of all the planets by the method of variation of orbital parameters. In 1783 he applied the same method to the derivation of the zeroth-order periodic inequalities (inequalities independent of the eccentricities and inclinations).

At this point Lagrange realized that his earlier proof of the immunity of the mean motions to secular variation needed qualification: the mean motions could appear to vary secularly owing to the secular variation of other orbital elements. Let the part of the apparent variation in the mean motion that is correlated with a change in mean solar distance, and is thus immune to secular variation, be $\mathrm{d}p$; this part is periodic and dependent on the positions of the planets. The other part, $\mathrm{d}\Sigma$, depends on the variations in other orbital elements, and is 'secular' (independent of planetary positions) when these other variations are. The variation $\mathrm{d}\Sigma$, Lagrange proposed, should be regarded as a variation in the sixth orbital element, the epoch.

$\mathrm{d}\Sigma$ proved to contain secular terms only when the approximation was carried to the second and higher powers of the eccentricities and inclinations. To mitigate the labor of such calculations, Lagrange proposed taking account only of terms that would be greatly augmented by integration. These were terms containing a cosine or sine of an angle π such that $\mathrm{d}\pi = \lambda\,\mathrm{d}p$, where λ is very small; for in the double integration such a term is multiplied by the large factor λ^{-2}. But π is a linear combination of the mean motions for the several planets, and a particular examination of these linear combinations will show which ones lead to small λ. Lagrange found no secular variation in $\mathrm{d}\Sigma$ that would account for Halley's secular accelerations. Laplace would shortly apply Lagrange's calculational proposal not to $\mathrm{d}\Sigma$ but to $\mathrm{d}p$.

Laplace's resolution of major anomalies, 1785–7

On 23 November 1785 Laplace announced the resolution of the anomaly in the mean motions of Jupiter and Saturn. J H Lambert had discovered that since the mid-seventeenth century the rate of Jupiter's acceleration, and the rate of Saturn's deceleration, were decreasing: the inequality could be periodic. Starting from the conservation of *forces vives*, Laplace now found that the secular variations Halley had proposed for these planets were in the ratio that their gravitational interaction would imply. As was well known, two periods of Saturn were nearly equal to five periods of Jupiter; the mean motions n_J and n_S therefore gave a linear combination, $2n_\mathrm{J} - 5n_\mathrm{S}$, that was very small. It followed that the periodic inequality proportional to $\sin[(2n_\mathrm{J} - 5n_\mathrm{S})t]$ could be sizable. On the other hand, its coefficient (which would consist of several terms) would be of the third dimension in the powers and products of the eccentricities and inclinations, and hence could be negligible. Only a complete calculation could decide the question. What Laplace found was the largest perturbation in the solar system, with a coefficient for Saturn of $-49'$, and for Jupiter of $20'$; the period was some 900 years. His new, augmented, theories for the two planets were in agreement with both ancient and modern observations.

Laplace's memoir of November 1785 included an explanation for a resonance Lagrange had discovered in the motions of the first three Galilean satellites of Jupiter, and also an attempted proof that the orbital eccentricities and inclinations of the planets must remain small. The latter proof, as LeVerrier later pointed out, tacitly assumed that all the planetary masses were of the same order of magnitude; it was therefore inconclusive.

By December 1787 Laplace had an explanation for the apparent secular acceleration of the Moon. The average radial component of the Sun's perturbing force is negative, subtracting from the Earth's attraction. The Earth's orbital eccentricity, owing to a secular but cyclical variation, is at present diminishing, causing a slight decrease in the Sun's average perturbing force. Hence the Moon is falling into a lower orbit and increasing its angular speed. Laplace's value for the increment, about 10" per century, agreed with the accepted empirical value. (This analysis was inadequate; see below.)

Laplace's *Mécanique Céleste*

The first four volumes of Laplace's *Mécanique Céleste*, which appeared between 1798 and 1805, contained not only an extended exposition of perturbation theory, but its detailed application to the planets and the Moon. For decades these volumes would serve as the textbook *par excellence* for mathematical astronomers. A strict accounting for all the detectable inequalities in the solar system appeared within reach. The masses of Mercury, Venus and Mars could be determined from perturbations. Evidently comets did not perturb the planets detectably.

Laplace achieved his successes by a mixture of methods, choosing one or another as it offered a swifter approach to a particular goal. His procedure for planetary inequalities proportional to the zeroth and first power of the eccentricities and masses was guaranteed to make a full sweep. To obtain the higher-order periodic inequalities, he proceeded by a kind of sharpshooting, which left uncertain whether all terms to a given order of smallness had been accounted for. He added the very long-term periodic inequalities to the mean motions, and used the thus modified mean motions in determining the short-term inequalities. The secular variations were determined by yet another procedure. This diversity of methods prompted the question: could not a single, demonstrably self-consistent procedure be adopted for the determining of all inequalities?

Meanwhile, workers in the Laplacian tradition had a clear enough task. The development of the perturbing function must be carried to higher orders of approximation, and the deduction of higher-order inequalities rendered more systematic. The Baron de Damoiseau and Giovanni Plana pursued these imperatives in their lunar theories. The planetary theories formulated by URBAIN J J LEVERRIER (1811–77) and, after him, by SIMON NEWCOMB (1835–1909), were descended from the same tradition, their distinction lying in their larger observational basis and greater precision.

The discovery of Neptune

The seventh planet, Uranus, was discovered by William Herschel in 1781. In 1821 Alexis Bouvard, in constructing a theory of Uranus, found he could not represent the observations with the expected accuracy of a few arcseconds. After 1821 the discrepancies grew, reaching nearly two arcminutes in the early 1840s. Was an unknown perturbing planet responsible?

In the mid-1840s JOHN COUCH ADAMS (1819–92) in England and LeVerrier in France independently undertook to respond to this question. They took the perturbing planet's orbit to lie in the ecliptic, Uranus's latitudes being minuscule. They accepted the Titius–Bode law, a numerical rule giving approximately the solar distances of the known planets, and implying that the next planet would have a mean solar distance of 38 astronomical units. Values for the orbital eccentricity and perihelion, epoch and mass of the unknown planet had then to be assigned so as to produce the perturbations that would bring Uranus's predicted motions into agreement with observation.

Both researchers succeeded. Adams, on presenting his results to GEORGE BIDDEL AIRY, the Astronomer Royal, in late 1845, met with rebuff: Airy distrusted the Titius–Bode law. LeVerrier sent his prediction to Johan Gottfried Galle of the Berlin Observatory, and on 23 September 1846 Galle turned his telescope to the indicated region of the sky, but failed to find the planetary disk he was seeking. His assistant, Heinrich Louis d'Arrest, suggested consulting the Berlin Academy's new *Star Atlas*. Comparing sky and chart, Galle located an eighth magnitude star not in the chart, 52′ from the position given by LeVerrier. On the 24th it had moved: it was the sought-for planet.

This discovery of Neptune by pure calculation was hailed as a triumph. The planet's orbit could now be calculated from observations. The mean solar distance proved to be 30.1 astronomical units: the Titius–Bode law was wrong. The orbital eccentricity was one-tenth as large as Adams and LeVerrier had supposed, and the perihelion over 100° distant from where they had put it. With the discovery of Neptune's satellite Triton in late 1846, Neptune's mass could be accurately determined; Adams's and LeVerrier's values were too large by factors of 2.65 and 1.88 respectively. Yet for the period from about 1800 to 1850, embracing the conjunction of 1821 between Uranus and Neptune when the perturbations were largest, Adams's and LeVerrier's hypothesized orbits were close to the actual orbit, gave very nearly the correct perturbations in this time-span, and permitted a correct pinpointing of Neptune's position.

The Lagrange–Poisson legacy: Hansen, Hamilton, Jacobi, Delaunay

In 1808 and 1809 Siméon-Denis Poisson (1781–1840) presented to the Paris Academy two memoirs utilizing and developing the Lagrangian method of variation of arbitrary constants. They stimulated Lagrange to further innovation. The Lagrange–Poisson theory was expounded in Lagrange's *Mécanique Analytique*, second edition (vol I, 1811; vol II, 1815).

Poisson introduced the concept of a 'conjugate momentum', p_i, for each coordinate q_i. If $q_i' = \mathrm{d}q_i/\mathrm{d}t$, and T is the kinetic energy, then $p_i = \partial T/\partial q_i'$. He showed that if a, b are two integrals of the system, the 'Poisson bracket'

$$(a, b) = \sum_{i=1}^{n} \left(\frac{\partial a}{\partial p_i}\frac{\partial b}{\partial q_i} - \frac{\partial a}{\partial q_i}\frac{\partial b}{\partial p_i} \right) \qquad \text{(LP.1)}$$

is independent of the time. He further showed that if a_i are the constants of integration that become variable under perturbation, then

$$\frac{\mathrm{d}a_i}{\mathrm{d}t} = \sum_{j=1}^{n} \frac{\partial \Omega}{\partial a_j}(a_j, a_i) \qquad \text{(LP.2)}$$

where Ω is the perturbing function. Poisson proposed and Lagrange proved that

$$\frac{\mathrm{d}a_i}{\mathrm{d}t} = -\frac{\partial\Omega}{\partial b_i}, \frac{\mathrm{d}b_i}{\mathrm{d}t} = \frac{\partial\Omega}{\partial a_i} \qquad \text{(LP.3)}$$

where the a_i can be the values of the q_i, and the b_i the values of the p_i, at $t = 0$. Equations of the form of (LP.3) would later be termed 'canonical'.

P A Hansen (1795–1874), director of the Seeberg Observatory from 1825 until his death, was a self-taught celestial mechanician. Because Laplace's formulae for perturbed coordinates held only to the first power of the perturbing forces, he soon turned to the method of variation of orbital parameters. This, however, had its own drawbacks: the perturbations of *six* elements had to be determined to find the perturbations of *three* coordinates, and the latter perturbations were often much smaller than the former, so that very small quantities had to be calculated from the differences of large quantities. Hansen sought to obtain a direct computation of the coordinates by rigorous derivation from the Lagrange–Poisson formulae.

The coordinates were functions of the orbital elements and the time; the orbital elements were functions of the time by (LP.2). Using the chain rule for partial derivatives, Hansen developed a two-part procedure. First he obtained the perturbed values of the longitude and radius vector in an instantaneous plane by substituting a 'perturbed time'—the time altered so as to incorporate the perturbative effects—into the standard elliptical formulae. Then he determined the position of the instantaneous plane relative to a plane of reference by means of the variations of two conjugated variables p and q.

Hansen first applied this procedure in a memoir on the mutual perturbations of Jupiter and Saturn; it won the prize of the Berlin Academy in 1831. (G W Hill in his more thorough computation of the Jovian and Saturnian perturbations in the 1880s would follow Hansen's procedure.) Hansen then turned to the lunar problem; his lunar tables, published in 1857, were adopted as the basis for the British and French national ephemerides from 1862 to 1922. The mathematician Arthur Cayley in the 1850s praised Hansen's procedure as the only rigorous treatment then available. Hansen's processes, however, were complicated; few astronomers understood them.

In two papers published in 1834 and 1835 in the *Philosophical Transactions* of the Royal Society of London, the Irish mathematician William Rowan Hamilton laid a new foundation for dynamics. He introduced the 'principal function' S, defined as

$$S = \int_0^t L\,\mathrm{d}t \qquad \text{(H.1)}$$

where $L = T - V$ is the 'Lagrangian', V being the potential energy. S, being evaluated along a solution curve of the differential equations of motion, must have an extremum value, so that $\delta S = 0$. The partial differential equation of the problem, it followed, was

$$\frac{\partial S}{\partial t} + H\left(q_1, \ldots, q_n, \frac{\partial S}{\partial q_1}, \ldots, \frac{\partial S}{\partial q_n}\right) = 0 \qquad \text{(H.2)}$$

where H is the 'Hamiltonian', or total energy, $T + V$. To the equations of motion Hamilton gave the canonical form

$$\frac{\mathrm{d}q_i}{\mathrm{d}t} = -\frac{\partial H}{\partial p_i}, \frac{\mathrm{d}p_i}{\mathrm{d}t} = \frac{\partial H}{\partial q_i}. \qquad \text{(H.3)}$$

The German mathematician C G Jacobi (1804–51) generalized Hamilton's theory, showing that it was applicable to non-conservative systems, and that a solution of the dynamical equations of motion was obtainable from a complete solution of (H.2). He also formulated a condition for transforming one set of canonical variables (obeying (H.3)) into another.

Independently of the work of Hamilton and Jacobi, CHARLES DELAUNAY (1816–72) in 1846 proposed determining the lunar perturbations from the initial equations

$$\frac{\mathrm{d}L}{\mathrm{d}t} = \frac{\partial R}{\partial l}, \frac{\mathrm{d}G}{\mathrm{d}t} = \frac{\partial R}{\partial g}, \frac{\mathrm{d}H}{\mathrm{d}t} = \frac{\partial R}{\partial h}$$

$$\frac{\mathrm{d}l}{\mathrm{d}t} = -\frac{\partial R}{\partial L}, \frac{\mathrm{d}g}{\mathrm{d}t} = -\frac{\partial R}{\partial G}, \frac{\mathrm{d}h}{\mathrm{d}t} = -\frac{\partial R}{\partial H}. \qquad \text{(D.1)}$$

Here (L, l), (G, g), (H, h) are six specially chosen orbital elements, conjugated in pairs in the manner of (LP.3), and R is the perturbing function. ((D.1) was a modification of a similar set proposed by M J Binet in 1841.) Delaunay developed R as a series of cosines of multiples of the relevant angles, to the seventh order of small quantities. His strategy in solving (D.1) was to separate R into two parts, R_1 and $R - R_1$, where R_1 is the largest term in R. He then solved (D.1) with R_1 substituted for R, obtaining new values of L, l, G, g, H, h, which he then substituted into $R - R_1$. Next, $R - R_1$ was to be separated into two parts, and the whole process repeated. At each stage, all the detectable effects due to the part of R under consideration were determined once for all—a major advantage over other methods, in which perturbational terms combined to produce new perturbational terms.

Delaunay's completed lunar theory appeared in two large volumes in 1860 and 1867. Like the earlier theories of Plana and P G D De Pontécoulant (1795–1874), it was a literal theory, giving the coefficients of perturbational terms in algebraic form rather than just numerically. Its chief disadvantage lay in the slow convergence of series.

The secular acceleration of the Moon revisited

In 1853 J C Adams showed that Laplace in his derivation of the Moon's secular acceleration had failed to take proper account of the tangential component of the Sun's perturbing force, and that when this was done, the overall effect deducible from the diminution in the Sun's perturbing force was only 6″ per century. Adams's result was confirmed by Delaunay in 1859. Astronomers

defending the Laplacian value were unable to demonstrate error in the Adams–Delaunay analysis. In 1865 Delaunay explained how the ocean tides raised by the Moon could slow the Earth's diurnal rotation: the tidal protuberances, being carried eastward of the Moon by the Earth's diurnal rotation, are attracted backward by the Moon, and friction between the tidal water and the solid Earth then tends to slow the Earth's rotation. Result: the Moon appears to accelerate.

The issue was settled in the twentieth century on the basis of ancient eclipses. The retardation in the Earth's diurnal rotation causes an apparent acceleration in the Moon of 20″ per century; this added to the Adams–Delaunay value gives a total acceleration of 26″ per century. The observed value is about 11″; the difference, 15″, is attributable to the reaction of the tides on the Moon, which raises the Moon into a higher orbit where its angular motion is less. Thus the Earth–Moon system evolves.

The lunar theory of G W Hill

The foundations for the century's most innovative lunar theory were laid by the American celestial mechanician GEORGE WILLIAM HILL (1838–1914) in two papers, 'Researches in the Lunar Theory' (1878) and 'On the Part of the Motion of the Lunar Perigee which is a Function of the Mean Motions of the Sun and the Moon' (1877).

Accuracy in earlier lunar theories was chiefly limited by slow convergence in the series giving the coefficients of perturbational terms; the culprit was the parameter m, the ratio of the sidereal month to the sidereal year. Hill's idea was to isolate the role of m and account for it fully at the start, by adopting a new first approximation, not the standard elliptical solution of the two-body problem, but a special solution of a 'restricted' three-body problem, in which the Moon is attracted but does not attract. Thus he set the solar eccentricity and parallax, the lunar eccentricity and inclination, all equal to zero, and used a rotating coordinate frame with origin at the Earth's center, x–y plane in the ecliptic, and x-axis constantly directed to the Sun. The resulting differential equations admitted of the particular periodic solution

$$x = \sum_i a_i \cos(2i+1)\tau$$

$$y = \sum_i a_i \sin(2i+1)\tau \qquad \text{(Hi.1)}$$

where $\tau = \nu(t - t_0)$, t_0 being the time at which the Moon crosses the positive x-axis and ν the frequency of its periodic motion about the Earth; the summations are extended to all integral values of i. By successive approximations, Hill determined the values of the a_i in rapidly converging series in the parameter $m' = m/(1-m)$; the error in these values, when m' was given the value it has for the Earth's Moon, did not exceed two units in the fifteenth decimal. (Hi.1) gives what Hill calls 'the variational orbit', since it embodies the principal part of the lunar inequality known as the variation.

To obtain an eccentric orbit like that of the real Moon, Hill in the second paper mentioned above introduced free oscillations about the radius vector of the variational orbit, and at right angles thereto. The oscillation δp along the radius vector is given by

$$\frac{d^2\delta p}{d\tau^2} + \delta p(q_0 + 2q_1\cos 2\tau + 2q_2\cos 4\tau + \cdots) = 0 \qquad \text{(Hi.2)}$$

an instance of what is now called Hill's equation. To obtain a particular solution in which τ does not appear outside the arguments of the cosines, a constant c must be inserted into the first approximation:

$$\delta p = A\cos(ct\sqrt{q_0} + \varepsilon) \qquad \text{(Hi.3)}$$

where c is the solution of an infinite but converging determinant. Hill obtained a value for c good to nearly the fifteenth decimal; it gives the motion of the lunar perigee as $0.008\,572\,573\,004\,864 \times 360^\circ$. In contrast, Delaunay's series for this constant, though carried to the term in m^9, yields a value accurate only to three significant figures.

With the superiority of Hill's method evident, E W Brown commenced in 1888 the process of developing a complete lunar theory by means of it. The resulting tables were published in 1919, and became the basis of the British and American ephemerides in 1923.

The work of Poincaré

The culminating theoretical achievement of nineteenth-century celestial mechanics was *Les Méthodes Nouvelles de la Mécanique Céleste* by HENRI POINCARÉ (1854–1912), published in three volumes from 1892 to 1899. Using Hamilton–Jacobi theory, Poincaré explored topologically the range of solutions to the three-body problem, starting (as had Hill) from periodic solutions. The topological approach was new. Issues raised by this work, in particular the convergence of series used in celestial mechanics, and the strange behavior of Poincaré's doubly asymptotic solutions, have resurfaced in the second half of the twentieth century in Kolmogorov–Arnold–Moser theory and in chaos theory.

Celestial Poles

The points on the celestial sphere at which the projected axis of the Earth intersects the sphere. The north celestial pole is thus vertically above the terrestrial north pole, and the south celestial pole vertically above the south terrestrial pole. The altitude of the north celestial pole is equal to the latitude of an observer on the Earth's surface, and since there is a star (Polaris, the Pole Star) close to the north celestial pole, it is possible for an observer in the northern hemisphere to obtain a rough estimate of his latitude simply by measuring the altitude of the Pole Star. Due to the rotation of the Earth, stars appear to move in circles centered on the celestial poles. Due to precession the direction of the Earth's axis changes and the position of the celestial poles changes as a result.

Celestial Sphere

An imaginary sphere of very large radius, centered on the Earth, and to which the stars are considered to be fixed for the purposes of position measurement. Due to the rotation of the Earth on its axis, the celestial sphere appears to rotate around the Earth once a day, and it is convenient to imagine that it is the Earth which is stationary, and the sphere which rotates. The sphere is therefore considered to rotate about an axis joining north and south celestial poles in an east to west direction (i.e. clockwise) at a rate of 15° per hour (of sidereal time). The plane of the Earth's equator, extended outwards to the sphere, marks the celestial equator. At any instant, an observer at a particular point on the Earth's surface can see only one half of the sphere. If he is located at one of the poles, one hemisphere is permanently below the horizon, while at the opposite extreme, if he is located at the equator, then each part of the sphere is visible at some time.

In ancient times, and up to the seventeenth century, it was widely accepted that the stars really were attached to such a sphere, which rotated round the Earth. Although we know that the stars lie at very different distances and that the celestial sphere has no real existence, it is still convenient to retain the concept of positional astronomy.

Cellarius, Andreas ($fl.$ seventeenth century)

Biographical details are unknown for Cellarius, who produced finest celestial atlas of the seventeenth century, the *Atlas Coelestis*, 1660, couched in terms both of the Ptolemaic and Copernican theories of the universe, for example a Ptolemaic view of the Earth as if seen through the starry sphere from an external distant point in space.

Celsius, Anders (1701–44)

Mathematician and astronomer, born in Uppsala, Sweden. As professor of astronomy at Uppsala he participated in MAUPERTUIS' expedition in 1736 to the most northern part of Sweden to measure the length of a degree of latitude along a meridian, close to the pole, and compare the result with measurements near the equator. The expeditions confirmed NEWTON's opinion that the shape of the Earth is an ellipsoid flattened at the poles. Founded the modern observatory in Uppsala in 1741, and made geographical measures, meteorological and astronomical observations. Realized that auroras have magnetic causes through correlation of the dip-angle of a compass needle with auroral activity. Published catalogs of the brightnesses of 300 stars using a photometer that attenuated a star's light until its extinction by a number of glass plates. For his meteorological observations he constructed the eponymous *Celsius thermometer*.

Centaurs

A group of objects in the outer solar system whose orbits cross those of the giant planets and are mostly confined between the orbits of Jupiter and Neptune. The first to be discovered was Chiron, in 1977, which was originally given the asteroidal designation (2060) Chiron. In 1989, seven years before perihelion, it was found to have developed a coma and was also given the cometary designation 95P/Chiron. Another object, (5145) Pholus, was found in 1992, and by April 2000 the total had reached 16. It may well be that the Centaurs are objects that have been perturbed inward from the Kuiper Belt, in a sense mirroring the relationship of the near-Earth asteroids to the main asteroid belt. Centaur orbits are unstable, and the fate of some of them may be further perturbation into the inner solar system as 'supercomets'. Their origin in the Kuiper Belt is supported by their reflectance spectra, which show them to be mostly dark red objects, and by their estimated sizes, which have a distribution consistent with that of Kuiper Belt objects. The largest may be (10199) Chariklo, with an estimated diameter of 300 km.

Centaurus

(the Centaur; abbrev. Cen, gen. Centauri; area 1060 sq. deg.) A southern constellation which lies between Vela and Lupus, and surrounds Crux on three sides. It culminates at midnight in early April. Its origin dates back at least to ancient Greece, where it was identified with Chiron in Greek mythology. The brightest stars of Centaurus were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large, conspicuous constellation, Centaurus is easily found. Its brightest star is α Centauri (Rigel Kentaurus, Toliman or Bungula), which at magnitude -0.3 is the third brightest star in the sky. It is actually a triple system consisting of a yellow (G2) primary, magnitude 0.0, an orange (K1) secondary, magnitude 1.4, separation 19.1″, period 81.2 years, and a third (M5) component, magnitude, 11.0, separation 2.2°, known as Proxima Centauri, which, at a distance of 4.2 light-years, is the closest star to the Sun. Other bright stars include β Centauri (Hadar or Agena), a close binary with components of magnitudes 0.6 and 3.9, separation 1.3″, θ Centauri (Menkent), magnitude 2.1, and γ Centauri (Muhlifain), another close binary with components both of magnitude 2.9 (combined magnitude 2.2), separation 1.2″, period 84.5 years. There are 18 other stars of magnitude 4.0 or brighter. Variable stars in Centaurus include the Mira-type stars R Centauri (range 5.3–11.8, period about 546 days) and T Centauri (range 5.5–9.0, period about 90 days).

Among several bright star clusters in Centaurus is ω Centauri (NGC 5139), a magnificent globular cluster, visible to the unaided eye as a fuzzy fourth-magnitude star. Other interesting objects include two open clusters, NGC 3766, which contains more than 60 stars between eighth and thirteenth magnitude, and NGC 5460, which has about 40 stars fainter than eighth magnitude, NGC 3918 (the Blue Planetary), an eighth magnitude planetary nebula described by John Herschel as 'very like Uranus, only half as large again', and NGC 5128 (Centaurus A), a seventh-magnitude elliptical galaxy and strong radio source, bisected by a dark dust lane. Centaurus also contains the x-ray binary Centaurus X-3.

Center for Astrophysical Research in Antarctica

The Center for Astrophysical Research in Antarctica (CARA) is operated by the US National Science Foundation Science and Technology Center and has its headquarters at the University of Chicago. The astrophysical observatory is located at the South Pole and is used to investigate the origin of structure in the universe.

Instruments deployed there take advantage of the cold, dry and stable conditions which make the Antarctic Plateau the best site on Earth for observations at infrared and submillimeter wavelengths. They allow small telescopes at the South Pole to outperform much larger telescopes at temperate sites.

Observations are made at microwave, submillimeter and infrared wavelengths. Instruments used to study the cosmic microwave background radiation include the Degree Angular Scale Interferometer and the Viper Telescope.

The 1.7 m Antarctic Submillimeter Telescope and Remote Observatory is used to observe molecular clouds, and the Submillimeter Polarimeter for Antarctic Remote Observing maps interstellar magnetic fields.

The 60 cm South Pole Infrared Explorer telescope and the Abu infrared camera demonstrate the site's potential for deep, wide-field, thermal infrared (2–5 μm) imaging of sources in the southern hemisphere.

Centre National d'Etudes Spatiales

The Centre National d'Etudes Spatiales (CNES) draws up, proposes and conducts France's space policy. Its role is to develop the uses of space, to meet the civilian and military needs of public bodies and of the scientific community, and to foster the development and dissemination of new applications, designed to create wealth and jobs.

CNES conducts French space policy by participating in the programs of the EUROPEAN SPACE AGENCY (ESA). In 1998, France's contribution to ESA represented 58% of the investment subsidy allotted to CNES and nearly 33% of all contributions made to ESA, placing France first among the Agency's contributors. France also plays a crucial role of proposal and training in the evolution of the ESA's objectives and the implementation of its programs. A national program is conducted which supplements the ESA's programs.

CNES has many different partners: space users, for whom it identifies and develops the space techniques and applications best suited to their needs; French industry, to which it gradually transfers its know-how in order to make it more competitive worldwide; laboratories of major scientific organizations with which it works on numerous research programs; defense agencies, alongside which it works to develop a defense program, thus creating synergy between civil and military programs; space agencies of other countries with which it cooperates, chiefly in scientific areas; and developing countries, whose involvement in the use of space technology for teaching, economic growth and resource management is backed by CNES.

The areas in which space policy is implemented are those which involve the major strategic and economic challenges: access to space, with the Ariane program—an ESA program whose launch services are marketed by Arianespace—and the creation of a launch base in French Guiana (Centre Spatial Guyanais, CGS); commercial applications such as Earth observation (Spot, ERS, Meteosat, IASI), and telecommunications (Télécom 2, Stentor, GNSS, Skybridge); scientific programs in conjunction with research institutions, based on European and international cooperation (Topex-Poseidon, Envisat, Jason, Polder, Scarab, Oersted, Cluster, Cassini-Huygens, Soho, Rosetta, Mars Express, Mars Sample Return); activities related to microgravity research and man in space (Perseus with Alice 2, Fertile and Castor, Pégase) and the preparation of experiments designed for the International Space Station; and defense related activities (Helios).

To conduct its operations, CNES has various centers, each featuring specific expertise and assignments: the Paris headquarters; the Launch Vehicle Directorate at Evry, responsible for the Ariane program; the Toulouse center, Centre Spatial de Toulouse, (CST), in charge of preparing and developing space projects for satellites and planetary vehicles, and for running operation facilities and large-scale infrastructures; the Guiana Space Center (CSG) in Kourou, French Guiana, a launch and test center; and balloon launch center (CLBA) at Aire-sur-l'Adour, in the Landes department of southwest France. CNES has 2500 employees spread over these sites.

The CNES budget stands at 13 169 million French Francs, including a state subsidy of 9115 million French Francs and its own resources of 4104 million French Francs. For nearly 20 years, CNES has formed commercial subsidiaries to sell the products and services turned out by space technology. These 20 companies directly employ a workforce of nearly 1000 people.

Cepheid Period–Luminosity Relation

The empirical correlation between the luminosity of a Cepheid variable and its period has been known to astronomers, and used by them as a powerful distance determination method, for the better part of the 20th century. Individually, Cepheids have distinctive light curves, rising rapidly in brightness to a maximum, and then falling more gradually to minimum light. This cycle consistently repeats with individual periods ranging from a few days to many hundreds of days, depending on the intrinsic brightness of the star. Collectively, the timescales over which this periodic cycling occurs for Cepheids are tightly coupled to the average luminosities of the stars. The reason for this empirical correlation is extremely well understood, and the applications of the period–luminosity relation are numerous. The implications, specifically for the extragalactic distance scale, are of importance in cosmology.

The period–luminosity relation for Cepheids was first discovered by the Harvard astronomer, Henrietta LEAVITT. She was analyzing the periods and apparent magnitudes of a selection of Cepheid variables all at a common distance in two of the (now known to be) nearby satellite galaxies to the Milky Way, the LARGE and SMALL MAGELLANIC CLOUDS. What Ms Leavitt found was to set in motion one of the most important and long-lasting astronomical activities of the 20th century—the calibration of the size scale of the universe. This was closely followed by the discovery of the expansion of the universe by Carnegie astronomer Edwin HUBBLE (see EXPANDING UNIVERSE), which, when combined, gave rise to a determination of the timescale to the creation of the universe, described by the 'hot big bang' model of modern COSMOLOGY.

Cepheids are supergiant stars, and as such they are among the most luminous objects in those galaxies that are today producing new populations of stars. The immediate precursors to Cepheids, according to stellar evolution theory, are the massive, young O- and B-type stars. These hot (blue) main sequence stars have been recently formed but, because of their high mass and prodigious energy output, they soon evolve away from the hydrogen-core-burning region to cooler surface temperatures and redder colors. In doing so, these enormous stars briefly pass through a zone in which their outer atmospheres are unstable to periodic radial oscillations. This narrow range of temperature triggering the atmospheric instability defines the so-called 'instability strip', where Cepheid pulsation can be observed. High-mass stars pass through the strip at higher luminosity (and slightly cooler temperatures) than lower-mass stars, which pass through the strip somewhat sooner at higher temperatures and at demonstrably lower luminosities. In the color–magnitude diagram the Cepheid instability strip slants upwards and across to the red.

Stated another way, these simple considerations from STELLAR EVOLUTION predict that a mass–luminosity relation exists for Cepheids. Indeed, it is also ensures that there is a radius–luminosity relation for these stars, since the most basic laws of physics demand that the only way for two stars of the same temperature (color) to have different luminosities is for the total surface areas (controlled directly by the radii) to be different. Since temperature implicitly controls surface brightness (through Stefan's law of emissivity, σT^4), and radius explicitly controls the surface area (through geometry, $4\pi R^2$), the combination of these two factors gives the total luminosity.

The interrelation between luminosity L, effective temperature $T_{\rm eff}$ and radius R is easily quantified by the following equation based on the physical arguments given above:

$$L = 4\pi R^2 \sigma T_{\rm eff}^4.$$

Given that the temperature at which these stars are unstable to oscillation covers a relatively small range ($\sim$300 K), luminosity then is primarily a function of the mean radius of the star in the instability strip. Unfortunately, neither the mass nor the radius of any star is an easily observed property, so the relation as written above cannot be used in any practical application for distance determinations (i.e. predicting intrinsic luminosities). If, however, some other (more directly observable) quantity were a function of the mass and/or the radius, one in principle could predict the luminosity using that quantity as a proxy for radius. With empirical hindsight we already know that there is a solution—the one found by Ms Leavitt—the period–luminosity relation. Theory easily explains this empirical relation.

Periods of oscillation at the surface of the Cepheid are intrinsic to the star and are obviously independent of the distance of the observer, but knowledge of an empirical period–luminosity relation immediately suggests that the observed period can be used to predict luminosity. From the physical arguments above, it must then be true that the period of oscillation can stand in for either mass or radius or some combination thereof. Indeed, this is the case.

However, nature provides us with even more; there is also an intrinsic period–color relation for Cepheids. Since both period (P) and color (C) are independent of distance, the P–C relation (once calibrated) is a means of detecting interstellar reddening in a sample of Cepheids in an external galaxy. Individually Cepheids can become redder and fainter owing to intrinsic temperature differences or redder and fainter because of line-of-sight extinction. For a collection of Cepheids, the intrinsic color differences will tend to average out. However, since extinction is a systematic effect, it will tend to move the entire population to redder and fainter levels. Compared with the intrinsic P–C relation the average deviation of the ensemble can be fairly interpreted as being due to interstellar extinction, and the inferred distance corrected for this absorption.

Explicitly correcting for systematic effects such as the dimming by interstellar dust (see INTERSTELLAR MATTER) is best accomplished by observing Cepheids at two or more wavelengths and using the period–color relations to predict statistical corrections for ensemble averages. An

alternative approach is to observe the Cepheids at long wavelengths where the effects of interstellar extinction are progressively diminished. For instance, by observing a Cepheid at 2 μm in the near-infrared, as opposed to the 4500 Å (blue) region of the spectrum, the effect of extinction drops by nearly a factor of 10.

For all freely oscillating systems, be they bells ringing, pendulum clocks swinging, planets orbiting, Cepheids pulsating, galaxies rotating, or even the entire universe expanding (or contracting), the primary physical determinant of the timescale (or oscillation period, P) is the mean density of the system (ρ). Density is, by its very definition, solely a function of mass and radius. The mathematical expression of this law of nature is captured in the equation

$$P\rho^{1/2} = Q.$$

At its most basic level, this equation is formally equivalent to the conservation of energy. Kepler's third law of planetary motion, linking the periods of planetary revolution about the Sun with their measured semimajor orbital axes, is another expression of this same formula (see KEPLER'S LAWS). Also, the relation between the expansion rate of the universe as characterized by the HUBBLE CONSTANT and the mean density of the universe compared with its critical density is the same formula in a cosmological setting.

The story behind setting a reliable zero point to the Cepheid P–L relation reads like a microcosm of the parallel quest to set a size scale to the entire universe. Indeed, these two tasks, disparate in scale, are often one and the same problem, recurrently interwined. In many contexts the Cepheid distance scale is the extragalactic distance scale. For instance, the HUBBLE SPACE TELESCOPE (HST) was, in large measure, designed around the expected use of Cepheids to reach galaxies and measure their distances as far out as the Virgo cluster some 10 or 20 times more distant than the most distant galaxies measured by Cepheids from the ground.

Measuring a Cepheid distance to Virgo was once hoped to be the Holy Grail of the distance scale, but this did not turn out to be the case. In the intervening years between the design of HST and its eventual launch and subsequent refurbishment, our view of the universe changed in a fundamental way: large-scale flows are now known to accompany the large-scale structures that fill the nearby universe. In other words, the velocities measured as redshifts for galaxies are not simply composed of a single Hubble expansion component, but they have superimposed flow velocities due to the gravitational perturbations of nearby matter in the form of nearby galaxies, groups and clusters.

The Key Project on the Extragalactic Distance Scale was premised on using Cepheids as distance indicators. Using traditional methods to discover extragalactic Cepheids by imaging in the optical (where the Cepheid amplitudes are large compared with redder wavelengths), the Hubble Space Telescope has been used by several groups including the Key Project to determine distances

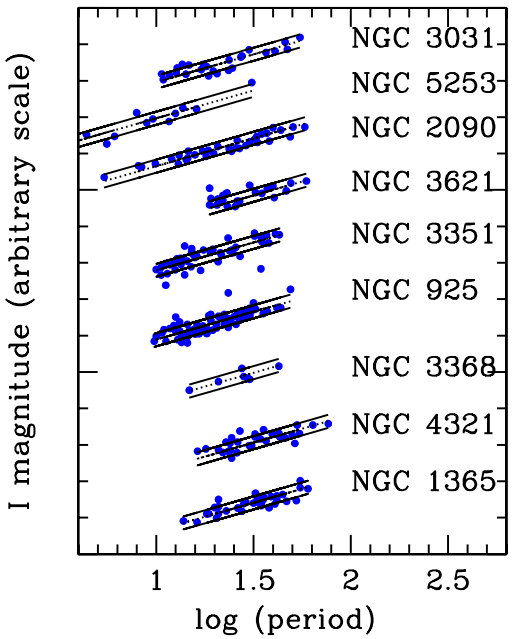

Figure 1. I-band period–luminosity relations for a sample of nearby galaxies (period in days).

to more than two dozen galaxies out to beyond the Virgo and Fornax clusters, nearly an order of magnitude further away than was previously possible using ground-based telescopes. The Cepheid distances to galaxies are then used to calibrate a number of secondary distance indicators for galaxies extending much further into the Hubble flow. With red (I-band) observations (see figure 1) the second color needed for extinction corrections was also obtained and true distances were derived. Follow-up studies of selected objects were also made at 1.6 μm with HST, using a near-infrared camera (NICMOS), to confirm the reddenings and strengthen the distance determinations based on a wavelength that is insensitive to both extinction and metallicity. The chemical composition, or metallicity, poses another plausible complication that needs to be addressed in evaluating the uncertainty associated with Cepheid distances. No significant differences were detected between the optically corrected true distance moduli and those bolstered by the near infrared data.

At the conclusion of the Key Project many secondary distance indicators were calibrated using Cepheid variables. Each of these methods yielded returned values of the expansion rate of the universe, the Hubble constant, falling between 68 and 78 km s^{-1} Mpc^{-1}. However, the distances (and velocities) to galaxies in and around the major clusters were also determined. Corrected for the perturbing effects of the clusters, these field galaxies also show a velocity–distance relation that can be identified with the expansion of the universe. From Cepheid distances alone one then can derive the strength of the relation between velocity and distance, and so locally it is

found to be 73 km s^{-1} Mpc^{-1}. This value of H_0, whether it is derived exclusively from Cepheids in galaxies nearby or from galaxies tied into the Cepheid distance scale but participating in the flow at 10 000 km s^{-1}, consistently suggest an age of 12 billion years for a low-density universe.

Cepheus

(abbrev. Cep, gen. Cephei; area 588 sq. deg.) A northern constellation which lies between Draco and Cassiopeia, and culminates at midnight in late August. It is named after King Cepheus, husband of Queen Cassiopeia and father of Andromeda in Greek mythology. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A rather inconspicuous constellation, the brightest star in Cepheus is α Cephei (Alderamin), magnitude 2.5. There are six other stars brighter than fourth magnitude, including three notable pulsating variable stars: β Cephei (Alfirk; range 3.16–3.27, period 0.19 day), a bluish-white (B2) star, which has a fainter, magnitude 7.8, companion, also bluish-white (A3), separation 13.3″; δ Cephei (the prototype Cepheid variable; range 3.48–4.37, period 5.37 days), a yellow (F5-G2) star, which has a bluish-white (B7) companion, magnitude 6.3, separation 41″; and μ Cephei (the Garnet Star—so called because of its intense red color; range 3.43–5.1, average period about 730 days).

Other interesting double stars in Cepheus include ξ Cephei (Kurhah), which has bluish-white (A3) and pale yellow (F7) components, magnitudes 4.3 and 6.4, separation 7.9″, and Krüger 60 , one of the nearest visual binaries (distance about 13 light-years), which has red (M3 and M4, dwarf) components, magnitudes 9.8 and 11.4, separation 3″, period 44 years, the fainter component of which (Krüger 60B or DO Cephei) is a flare star (max. 10.3). A bright Mira-type variable star is T Cephei (range 7.4–12.9, period about 487 days).

Open clusters in Cepheus include NGC 7160, which contains a couple of dozen stars fainter than seventh magnitude, and NGC 188, which has more than 150 stars between tenth and eighteenth magnitude and is one of the oldest galactic clusters known (estimated age around 9000 million years). There are no bright nebulae or galaxies in the constellation.

Ceres

The first asteroid to be discovered, by Giuseppe Piazzi on 1 January 1801, and so designated (1) Ceres. The discovery resulted from a search prompted by Bode's law, a numerical relationship between the known major planets which suggested a 'missing planet' between the orbits of Mars and Jupiter. Ceres is by far the largest of the asteroids, with a diameter of 933 km, and accounts for over one-quarter of the mass of the entire main-belt asteroid population. It orbits the Sun at a mean distance of 2.77 AU (414 million km) in a period of 4.60 years; the orbital inclination is 11º, and the eccentricity 0.08. Ceres rotates in 9.08 h, and has a density of 2.7 g cm^{-3}. It is a G-type asteroid, with a reflectance spectrum similar to that of carbonaceous chondrites, and an albedo of 0.11.
See also: BODE'S LAW.

Web update

Recent observations at the European Southern Observatory with the world's first operational virtual telescope 'Astrovirtel' have determined that the newly discovered distant asteroid 2001 KX76 is significantly larger than Ceres. Ceres, the first asteroid (minor planet) to be discovered in the Solar System, has held the record as the largest known object of its kind for two centuries with a diameter about 950 km. Asteroid 2001 KX76 has been found to have a diameter of 1200 km, possibly even 1400 km.

CERN

CERN—the acronym comes from the original French name 'Conseil Européen pour la Recherche Nucléaire—the European Laboratory for Particle Physics, is one of the world's most prestigious research centers. Its business is fundamental physics, i.e. finding out what makes our universe work, where it came from, and where it is going. At CERN, some of the world's biggest and most complex machines are used to study nature's tiniest building blocks. By colliding these minute particles of matter, physicists unravel the basic laws of nature. Amongst other areas of applicability, CERN's research is used in astroparticle physics, with relevance to studies of dark matter, the Big Bang, etc. This research is purely scientific and the results are freely available.

CERN's machines are particle accelerators and detectors. The laboratory's accelerator complex is built around three principal inter-dependent accelerators. The oldest, the Proton Synchrotron (PS), was built in the 1950s and was briefly the world's highest energy accelerator. The Super Proton Synchrotron (SPS), built in the 1970s, was the scene of CERN's first Nobel prize in the 1980s.

Ground-breaking research was performed at the Large Electron Positron collider (LEP) throughout the 1990s. The extraordinary quantity of high-precision results from LEP highlighted the possibility of exciting future discoveries, such as finding the Higgs particle, postulated to confer mass on the particles of matter, and supersymmetry, a profound extension to the relationship between particles of matter and particles carrying the fundamental forces between them.

Fundamental research is CERN's reason for being, but the laboratory also plays a vital role in developing the technologies of tomorrow. From materials science to computing, particle physics demands the ultimate in performance, making CERN an important test-bed for industry. The quality of the technology developed by the laboratory is becoming more and more widely recognized. Today everyone knows the World Wide Web, but not many know that it was invented at CERN, conceived to give particle physicists easy access to their data wherever they happened to be on the planet. The World Wide Web, medical imaging, or advanced techniques for using electronic chips, are just a few of the many recent spin-offs from the fundamental research carried out at CERN.

The next stage in Europe's strategy for particle physics is the Large Hadron Collider (LHC). CERN Council's decision on 16 December 1994 to build the LHC, which has the potential to make some of the most important scientific discoveries of our era, was a milestone in the history of particle physics and of CERN. The LHC is a technologically challenging, superconducting accelerator which will bring protons into head-on collision at higher energies than ever achieved before. It will be installed in the 27 kilometer tunnel that at present houses the LEP collider. Preparations for the LHC are moving ahead at full speed, with several thousand physicists worldwide actively preparing for its arrival, expected in 2006. The tremendous technological challenges facing those who are building the LHC and its detectors are an important driving force for innovation in European industry.

The laboratory sits astride the Franco-Swiss border, west of Geneva, at the foot of the Jura mountains, and was founded in 1954 as one of Europe's first joint ventures. Since then it has become a shining example of international collaboration. From the original twelve signatories of the CERN convention, membership has grown to twenty member states: Austria, Belgium, Bulgaria, the Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Italy, the Netherlands, Norway, Poland, Portugal, the Slovak Republic, Spain, Sweden, Switzerland and the United Kingdom. In 2001 these countries contributed to an annual budget of 1050 million Swiss francs in amounts proportional to their net national income.

Cerro Tololo Inter-American Observatory (CTIO)

CTIO is operated by the ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY Inc. (AURA), under a cooperative agreement with the National Science Foundation as part of the National Optical Astronomy Observatories.

The Observatory is about 2200 m above sea level, and 500 km north of Santiago in Chile. Its headquarters are located at La Serena.

On site are six optical telescopes and one radio telescope. The largest instrument is the 4 m Victor M Blanco Reflecting Telescope, whose twin is located at KITT PEAK OBSERVATORY in Arizona. This telescope has been in operation since the early 1970s.

Other instruments at the site include a 1.5 m Ritchey–Chrétien telescope, the YALO 1 m Ritchey–Chrétien telescope, a 92 cm reflector, a 0.6/0.9 m Curtis/Schmidt telescope, the 60 cm Lowell Telescope and 'El Enano' (The Dwarf), the smallest telescope on Tololo.

The 1.2 m radio telescope of the Universidad do Chile is also at the site.

For further information see http://www.ctio.noao.edu/ctio.html.

Cetus

(the Sea Monster or Whale; abbrev. Cet, gen. Ceti; area 1231 sq. deg.) An equatorial constellation which lies between Aquarius and Taurus, and culminates at midnight in October. It is named after the sea monster from which Perseus rescued Andromeda in Greek mythology, though it is sometimes identified as a whale. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

Although the fourth largest constellation, Cetus is rather inconspicuous, its brightest stars being β (Diphda), magnitude 2.0, and α (Menkar), magnitude 2.5. There are seven other stars of magnitude 4.0 or brighter. Interesting stars in Cetus include the prototype long-period variable o Ceti (Mira; range 2.0–10.1, period about 332 days), the flare star UV Ceti (rest magnitude 12.9, max. 6.8) and τ Ceti, magnitude 3.5, one of the two closest Sun-like stars (distance about 11.8 light-years—the other being ε Eridani).

Another interesting object in Cetus is M77 (NGC 1068), a ninth-magnitude spiral galaxy (the brightest Seyfert galaxy).

CH Cygni

CH Cygni (CH Cyg) is one of the most enigmatic SYMBIOTIC STARS. Once known as a short-period semiregular variable and standard for the M6 III spectral type, the system began an unusual series of eruptions in 1964. The appearance of a blue continuum and modest H I emission lines led to its reclassification as a symbiotic star despite its lack of the strong higher ionization lines characteristic of most symbiotics. Some of these lines were later discovered with higher-quality spectra acquired in the 1970s and 1980s. Even so, the erratic behavior of the system during quiescence and eruption clearly distinguishes CH Cyg from most symbiotic stars.

CH Cyg has properties in common with *o* Ceti (MIRA) and the symbiotic star R Aqr, two M6–M7 type giants with a white dwarf companion. All are relatively nearby, with distances of 100–300 pc compared with the 1 kpc distance of the typical symbiotic binary. The systems contain pulsating RED GIANTS with periods of ∼100 days in CH Cyg and ∼1 year in Mira and R Aqr; all have orbital periods of decades to centuries. The combination of a late-type giant and a long orbital period in a nearby binary produces interesting behavior not observed in other symbiotic stars, such as Z ANDROMEDAE. Studying this evolution has been very popular; understanding it has proved elusive.

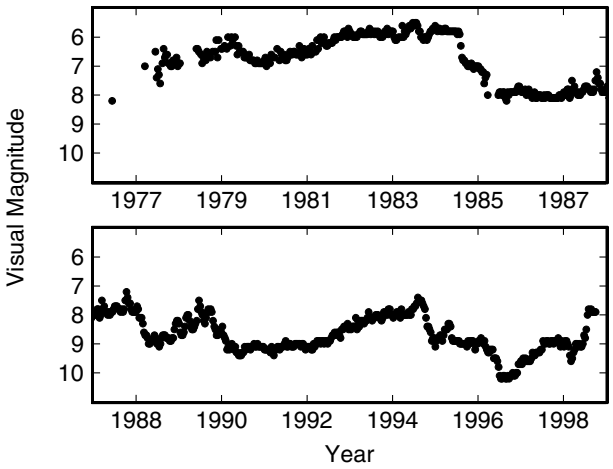

Figure 1. Recent optical light curve of CH Cyg using 10 day means of observations from the AFOEV and VSNET databases. Jet ejection began during the step-like drop in brightness bracketing 1985 in the right corner of the upper panel.

Basic properties

CH Cyg displays a bewildering array of photometric variations. Short-timescale fluctuations are observed at optical and x-ray wavelengths. The optical variations are coherent, with a period of 2500–3000 s and an amplitude that increases from ∼0.02 mag at 7000 Å up to ∼0.3 mag at 3600 Å. X-ray observations indicate a non-variable, soft component with $kT \sim 0.4$ keV and a variable component with $kT \sim 7$ keV. The x-ray variability occurs on timescales as short as 300 s but is not coherent.

Longer timescale variations are also present (figure 1). Semicoherent variations with periods of ∼100 days, ∼770 days, ∼1300 days and ∼32 years appear in the optical and near-infrared light curves. The typical amplitude of these changes is ∼0.5 mag in the optical and ∼0.25 mag in the near-infrared. The amplitudes and phases of these variations change from one decade to the next. Several studies have proposed an additional period of 5700 days produced by eclipses of the emission line source by the red giant star. The optical colors of the system are usually redder during the eclipse.

There is good evidence for RADIAL VELOCITY variations phased with several of the photometric periods. Velocities derived from red giant absorption features indicate periods of ∼760 days and ∼5500 days. The shorter period is similar to the orbital periods of other symbiotic stars. The derived mass function is also comparable with that of other symbiotics if the velocity variations are due to orbital motion. Unlike most symbiotics, however, this period is not always present in the light curve. Irregular light and velocity variations are often observed in single late-type giants, so this period might be a pulsation period or (much less probably) a rotation period. The longer period has more support as the true orbital period of the system. Orbital conjunctions coincide with minima in the emission line intensities. The jet ejection events described below also seem phased with this period. The velocity amplitude leads to reasonable masses for the red giant, 1–3 $M_\odot$, and for the hot component, 0.5–1.0 $M_\odot$.

The spectroscopic variations of CH Cyg are fortunately more tame than the photometric variations. The spectrum always shows evidence for an M-type giant, with a strong red continuum and deep TiO absorption bands. The spectral type of this component varies between M5 and M7. The hot component has three states: (i) an inactive state where the blue continuum and emission lines are absent or barely detectable; (ii) a low state where the blue continuum and H I emission lines are relatively weak; (iii) a high state where the blue continuum is strong and resembles the spectrum of an F-type supergiant (figure 2). Modest H I and Fe II emission lines accompany the F-type continuum in the high state. Some high ionization lines, such as [O III] in the optical and C IV in the ultraviolet, are present during the high and low states. These lines are usually stronger during the low state than the high state, as in other symbiotic stars. However, the emission lines always appear to be weaker relative to the UV or optical continuum than in other symbiotic stars. The origin of this difference is unknown.

The emission line profiles of CH Cyg are complicated and highly variable. Most lines indicate mass motions with velocities of 100–200 km s^{-1}. These lines are usually symmetric about the systemic velocity, but sometimes display extra emission with positive or negative velocity. When the H I lines are strong, they often have broad profiles with deep central absorption reversals. These

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

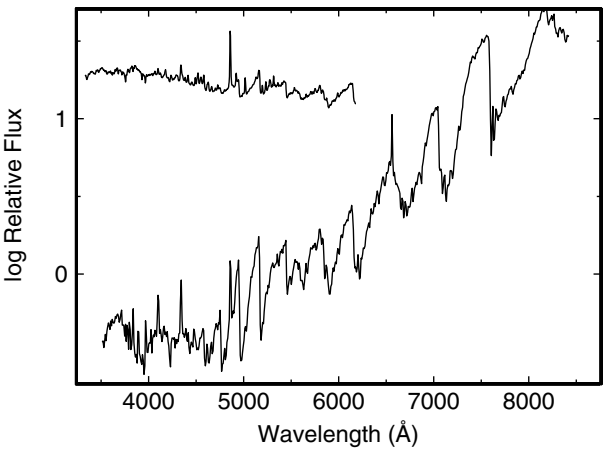

Figure 2. Spectra of CH Cyg in the low state (lower curve) and the high state (upper curve). The low-state spectrum resembles that of a normal M6 giant with weak H I emission lines and a variable blue continuum. In the high state, the blue continuum rises by more than a factor of 10 and resembles that of an F-type supergiant with modest H I emission lines. The right half of the high-state spectrum has been omitted for clarity; it blends smoothly into the low-state spectrum at roughly 7000 Å.

profiles resemble emission lines observed in dwarf NOVAE and other cataclysmic variables. However, the lines often become single peaked, which is not typical of dwarf novae. The variability of the H I lines may be associated with the complex photometric variations, but the available data are not extensive enough to make a clear association with any of the photometric periods.

Surprisingly, some of the most interesting activity of CH Cyg occurs during low states. In 1984, the hot component began to eject material at high velocities shortly after a 2–3 mag drop in the optical brightness. As the F-type continuum and several emission lines faded during this decline, the star developed strong [O III] emission lines indicating material moving at velocities of $\sim$500 km s^{-1}. The intensity of 1–10 cm radio continuum emission increased by a factor of 3 in roughly 1 month. Nearly all of this radio emission was confined to two knots of gas moving away from the central star at a projected velocity of $\sim 1000(d/200\,\mathrm{pc})$ km s^{-1}. This ejection is similar to the bipolar jets observed in ACTIVE GALACTIC NUCLEI and PRE-MAIN-SEQUENCE STARS. Spatially resolved optical spectra clearly associated the [O III] emission with the radio knots. The radio emission declined as the knots moved away from the central source and then rose slightly as the source ejected a second, smaller set of knots moving at the same velocity. This event began $\sim$200 days after the first ejection and was accompanied by a factor of 2 decline in the optical brightness. A third small ejection began $\sim$200 days later but was not associated with a drop in brightness. All of these knots faded over several years, when the system resumed its 'normal' low-state spectrum.

Jet formation associated with a significant drop in the optical brightness began again in 1997–1998. Several optical emission lines simultaneously developed broad features indicating mass motions with velocities of 500–1000 km s^{-1}. The system recovered quickly, rising by 1.5 mag in the ultraviolet during May–July 1998. The 14 yr interval between the two radio outbursts is 1–2 yr shorter than one of the proposed orbital periods.

Interpretation

The origin of CH Cyg's bizarre behavior is unclear. Three emission states—inactive, low and high—are unusual: most symbiotics have low and high states. Multiple strong periodicities in the light curve are also rare. The weak emission line spectrum is atypical, although Mira and a few other symbiotics have similar emission line spectra.

The current picture for the CH Cyg system begins with an interacting binary composed of an M-type giant and a hot WHITE DWARF. The white dwarf accretes material lost by the giant. Energy generated by ACCRETION powers the observed activity. Irregular pulsations of the giant modulate the accretion rate onto the white dwarf, which varies the activity level. It is unlikely that the white dwarf generates much energy by thermonuclear burning of the accreted mass: the luminosity at maximum, $\sim 100 L_\odot$, is small for a white dwarf with a nuclear burning shell.

Adding finer details to this picture has been difficult. Two variants have been proposed. The first envisions a wide binary with an orbital period of $\sim$5500 days. A pulsating red giant is responsible for the $\sim$100 day and the $\sim$700 day periods. A magnetic white dwarf—similar to the white dwarf in Z And—rotates with a period of 2500–3000 s. Accretion onto the magnetic poles of this white dwarf produces the short-timescale variations. Inactive states occur near apastron, when the white dwarf is far away from the red giant and the accretion rate is low. These states are long lived, because the binary spends most of its time at apastron. Active states occur near PERIASTRON, when the accretion rate is high. In this model, cycling between the low and high states results from an imbalance between the magnetic pressure of the rotating white dwarf and the ram pressure of material in the red giant wind. High states occur when the ram pressure exceeds the magnetic pressure. Accretion onto the white dwarf then produces the F-type continuum, although the physical mechanism producing this continuum is unclear. Low states occur when the magnetic pressure exceeds the ram pressure and prevents accretion onto the white dwarf. This 'propeller' mechanism also drives the bipolar jets by a process which is poorly understood at best.

A second concept considers CH Cyg as a triple system. In this model, the red giant and white dwarf inhabit a close binary with a 760 day period. A mundane G dwarf orbits this binary with a 5500 day period. Variants of this picture replace the G dwarf with another M giant, but spectroscopic evidence for two red giants in the system is not compelling. A triple system provides a natural explanation for two persistent modulations of the system, 760 days and 5500 days. Red giant pulsations are still necessary for other long periods; a magnetic white dwarf

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is still responsible for the 2500–3000 s optical pulsation. An advantage of this model is that the close inner binary is similar in structure to a typical symbiotic star. The enhanced mass transfer possible in a closer binary could power the unusual activity of the hot component. A propeller model could still give rise to cycling between high and low states, but the origin of the inactive state is unclear. Other symbiotics stars with ∼700 day orbital periods are never inactive. Short periods of *apparent* inactivity in some symbiotics occur when the red giant occults the hot component. The most popular version of the triple-star model proposes that both red giants eclipse the hot component to produce inactive periods. This geometry is *a priori* unlikely and may not produce long enough inactive periods. Explaining the jet activity in the low state is also a challenge, because almost all other symbiotics eject more material in high states than low states.

Most analyses of CH Cyg have concentrated on photometric data. Detailed models of spectroscopic data will be needed to understand the energetics of the hot component and the dynamics of the NEBULA. Neither proposed model for CH Cyg makes many predictions for future behavior of the system; further work may point to better tests of the models and allow a definitive choice to be made between them.

CH Stars and Barium Stars

The classical barium (or 'Ba II') stars are RED GIANT STARS whose spectra show strong absorption lines of barium, strontium and certain other heavy elements, as well as strong features due to carbon molecules. Together with the related class of CH stars, the Ba II stars were crucial in establishing the existence of neutron-capture reactions in stellar interiors that are responsible for the synthesis of heavy elements. More recently, the Ba II and CH stars have provided strong evidence for mass transfer in binary systems that drastically alters the surface composition of a companion star.

Barium stars

Ba II stars were first recognized by W P Bidelman and P C Keenan in 1951. They are G-K giants whose spectra show an unusually strong absorption line of Ba II at 4554 Å, along with enhanced lines of Sr II and molecular bands of the CH, C_2 and CN molecules. The prototype is the third-magnitude star ζ Capricorni. During the ensuing decade, studies of the spectra at high dispersion revealed that the abundances of numerous heavy elements are enhanced, notably the elements Sr, Y and Zr; rare earths such as La, Ce, Nd and Sm; and of course Ba. It was soon realized that these are exactly the elements expected to be synthesized when 'seed' nuclei in the iron group are exposed to a flux of neutrons and are thus built up to higher atomic weights, on a timescale that is slow compared to the beta-decay timescale. This so-called '*s*-process' leads to high abundances of those chemical elements with low neutron-capture cross sections (these being the 'bottlenecks' in the neutron-capture chain), which are exactly the elements in the atomic-weight peaks around Sr and Ba.

CH stars

The CH stars are a closely related class, actually first recognized even earlier than the Ba II stars by P C Keenan in 1942. They are essentially the Population II counterparts of barium stars, having similar enhancements of *s*-process elements and very strong bands of the CH molecule (see also POPULATION II STARS). However, CH stars have weak lines of the ordinary metals such as iron, since these stars belong to the old, metal-deficient population of our Galaxy.

CH stars are found both in the Galactic halo and in several globular clusters. The cluster ω Centauri contains the richest population of CH stars, about half a dozen.

The luminosity problem

By the early 1970s, the nucleosynthetic origin of the enhanced chemical elements in the Ba II and CH stars was reasonably well understood: they arise in stellar interiors when a flux of neutrons irradiates iron-group seed nuclei. This can happen, for example, during mixing associated with helium thermal pulses which brings together ^{13}C nuclei and alpha particles; each reaction releases a ^{16}O nucleus and a free neutron. Carbon is synthesized during helium burning in the cores of red giants. Subsequently, a mixing process causes the products of these reactions to be exposed at the stellar surface. In the mid-1970s, however, detailed calculations of stellar evolution revealed a severe evolutionary problem: the sort of mixing required (called the 'third dredge-up') only occurs in highly evolved, luminous asymptotic-giant-branch (AGB) stars. Yet the Ba II and CH stars were known to have only the luminosities of ordinary red giants, far too faint for any dredge-up to occur.

The problem was exacerbated by the discovery in 1974 by H E Bond of what he called 'subgiant CH stars,' which are F- and G-type stars of even lower luminosities, extending in some cases down to the main sequence, and showing similar patterns of enhanced heavy elements and carbon. Subsequent work has suggested that 'dwarf barium stars' would be a better name for most of the members of this class, since most of them are not extremely iron-deficient. Even further down the main sequence, at spectral type K, a class of 'dwarf carbon stars' was discovered in the late 1970s. All of these objects are far too faint to have synthesized *s*-process elements and carbon in their own interiors, let alone to be mixing them up to the stellar surface.

Moreover, none of these objects appear to be particularly rare stars; for example, large-scale spectroscopic surveys show that about 1% of red giants are members of the Ba II class, and a similar fraction of F-G dwarfs are barium dwarfs or subgiant CH stars.

The solution

The solution to the luminosity problem came in the early 1980s, when R D McClure and his collaborators established that virtually all Ba II and CH stars are spectroscopic binaries, with fairly long periods and typical orbital separations of the order of 2 AU. This led to the realization that the binary system once contained an AGB star that mixed carbon and *s*-process elements to its surface, and then transferred this 'polluted' material to a companion star. In many cases the companion would have been on or near the main sequence, and it is now seen as a dwarf barium star, dwarf carbon star or subgiant CH star. When the contaminated main-sequence star evolves to become a red giant (or if the mass transfer is from the AGB star directly to a red-giant companion), it will be seen as a classical red-giant Ba II star (or as a CH star if the binary is a metal-poor member of Population II).

The solution confirmed

A direct test of the binary scenario would be to find a white-dwarf companion of a barium star. The above scenario in fact *demands* that all of the companions be white dwarfs, i.e., the remnants of the former AGB star.

In a stunning confirmation of the scenario, E Böhm-Vitense showed in 1980 that ζ Cap has a hot white-dwarf companion, revealed in the ultraviolet by the INTERNATIONAL ULTRAVIOLET EXPLORER satellite. Subsequent UV observations with IUE, and more recently by Böhm-Vitense and her collaborators with the HUBBLE SPACE

TELESCOPE, have revealed several more examples of Ba II stars with white-dwarf companions. In many cases, however, the white dwarf has faded to below detectability, and its presence shows up only in the variable radial velocity of the peculiar optical star.

The pollution mechanism

Recent work on the Ba II and related stars has focused on the precise mechanism by which the AGB star contaminates its innocent companion. The two main possibilities are (a) that the AGB star evolves to fill its Roche lobe, and then spills substantial amounts of its envelope material onto the companion; and (b) that the AGB star pollutes the companion only through a stellar wind. In scenario (a), the outcome would usually be a common-envelope interaction, with a spiralling down of the orbit to a much smaller separation, so that the binary emerges as a cataclysmic variable rather than a barium star. However, some authors have argued that stable Roche-lobe overflow is possible, thus avoiding the spiral-down. Scenario (b) is probably more likely at least for most barium stars, both because of their still large orbital separations and because many of them have somewhat eccentric orbits, which would not be the case following Roche-lobe overflow.

Bibliography

Ba II stars were discovered by

Bidelman W P, and Keenan P C 1951 The Ba II stars *Astrophys. J.* **114** 473–6

A comprehensive review article covering work through the early 1980s, including the first demonstration that most or all Ba II stars are spectroscopic binaries, was written by

McClure R D 1984 The barium stars *Pub. Astron. Soc. Pacific* **96** 117–27

CH stars were first recognized by

Keenan P C 1942 The spectra of CH stars *Astrophys. J.* **96** 101–5

Subgiant CH stars were defined by

Bond H E 1974 The subgiant CH stars *Astrophys. J.* **194** 95–107

The first dwarf carbon star was discovered by

Dahn C C *et al* 1997 G 77-61: A dwarf carbon star *Astrophys. J.* **216** 757–66

Details of the formation of Ba II and CH stars have been discussed by

Han Z, Eggleton P P, Podsiadlowski P and Tout C A 1995 The formation of barium and CH stars and related objects *Mon. Not. R. Astron. Soc.* **277** 1443–62

Chamaeleon

(the Chameleon; abbrev. Cha, gen. Chamaeleontis; area 132 sq. deg.) A southern constellation which lies between Carina and the south celestial pole, and culminates at midnight in early March. It was first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, the brightest stars in Chamaeleon are α and γ Chamaeleontis, both magnitude 4.1. Interesting objects include δ Chamaeleontis, a wide double star with bluish-white (B2.5) and orange (K0) components, magnitudes 4.5 and 5.5, separation about 6′, the fainter of which (δ^1) has a fainter companion, and NGC 3195, a twelfth-magnitude planetary nebula.

Chandra X-ray Observatory

Launched on 23 July 1999 on board the Space Shuttle Columbia from Cape Canaveral, the Chandra X-ray Observatory is the first x-ray astronomy telescope to match the 1/2 arcsecond imaging power and the 0.1% spectral resolving power of optical telescopes. Chandra is named after Subramanian Chandrasekhar, known as Chandra, and author of the Chandrasekhar limit. Chandra has been extremely successful and productive so far. (See http://chandra.harvard.edu for many examples.)

Any experiment that is 10 or 100 times better than its predecessors is virtually certain to make revolutionary discoveries and CHANDRA is demonstrating this truism dramatically. Examples include settling decade-old debates with a single observation: yes cometary x-rays are due to charge exchange; no, most elliptical galaxies do not have much hot gas in their interstellar medium, but they do have their quota of compact binaries; no, cooling flows in clusters of galaxies only cool so far (down to 2×10^7K); and yes, the COSMIC X-RAY BACKGROUND is made up of the light from many quasars—about 1000 in each area of sky the size of the Moon.

Other examples are of completely new discoveries still to be checked out with further studies: a type of quasar that, perversely, is obscured in x-rays, but shines through clearly in optical light; spectral absorption lines that seem to come from a bath of hot gas that our Milky Way galaxy, and the whole of our Local Group of galaxies, is lying in. (There appears to be so much of this 'Warm Hot Intergalactic Medium' or 'WHIM' that it could even be the 'missing mass' that binds the Local Group galaxies together); the relativistically moving jets from quasars shine brightly in Chandra images, as long as clusters of galaxies are across, and brighter when they are further away, thanks to the higher temperature and intensity of the Cosmic Microwave Background, so there are more of these photons to be scattered off the fast moving electrons of the jet, so gaining enough energy to become the x-rays we see. Then there are the nests of super-bright x-ray binaries in starburst galaxies that appear to exceed the EDDINGTON LIMIT of luminosity if they have a normal 10 solar mass black hole in them. Could they imply a new and predicted-not-to-exist population of intermediate mass (100–10(4) solar masses) black holes? The spectra of a neutron star (i.e. one not in a binary or a supernova remnant) shows a black body spectrum with a well determined temperature, together with its distance gives the luminosity and so combining them the area of the NEUTRON STAR. This could be the first example of a new type of star and a new type of matter, a QUARK STAR.

Chandra's resolution leads to 100 times more sensitivity over earlier x-ray missions because background light is imaged away allowing much fainter sources to be seen, and also creates the good spectral resolution. Chandra's resolution stems from its unprecedented x-ray mirror. The x-rays that Chandra images span 0.1–10 keV (12–0.12 nm). X-ray optics only reflect x-rays if they strike glancingly, at about 1°. So x-ray mirrors only bend light slightly, giving x-ray telescopes large f ratios, 8.3 for Chandra. So Chandra's 1.2 m diameter mirror has to have a focal length of 10.070 m. To increase Chandra's area four sets of almost cylindrical mirror shells are nested within one another, giving a total of 800 cm^2. To improve their reflectivity they are coated with iridium, a high-Z, high-density element. Since two reflections are needed to make an image, Wolter type 1 parabolas/hyperbolas are used. With photon wavelengths of only a few nm the mirror surfaces must be smoother than this (<0.04 nm for Chandra), else photons would be scattered to large angles, blurring the image.

To disperse the x-ray spectrum, Chandra has three sets of transmission diffraction gratings, optimized for low (LETG), medium (MEG) and high (HEG) energies. They all have line densities of about 1000 mm^{-1}, and are constructed using semiconductor technology. The gratings behave like objective prisms, making an image of the source for each wavelength. Since a star makes a small image in Chandra, different wavelengths are well separated.

Chandra has two types of detectors: 'ACIS' is made from charge-coupled devices (CCDs), cousins of video cameras CCDs; 'HRC' is made from microchannel plates, used in night vision goggles. HRC can time the arrival of x-ray photons to 16 ms, has the smallest pixels (0.4 arcsec) and has a large (30 arcmin × 30 arcmin) field of view. The HRC has sensitivity to low-energy photons (to E~0.05 keV), and so is used to image the spectra from LETG. ACIS has better efficiency and energy resolution. ACIS uses two types of CCD chips: 'frontside illuminated' (FI) which detect higher energy (E>1 keV) x-rays have low background, while 'backside illuminated' (BI) work well (QE>0.5) down to 0.5 keV. X-ray CCDs determine the energy of each x-ray from the number of electrons it produces. An accidental exposure of the main 16 arcmin × 16 arcmin array of four FI CCDs to energetic (100 keV) protons in the solar wind just after launch degraded their energy resolution. Much of this resolution has been regained by cooling the chips and by special software. The smaller 8 arcmin × 8 arcmin BI chip was unaffected.

Because every photon is recorded individually, x-ray images have four dimensions: position (x,y), energy and time. So, unlike the Hubble Space Telescope, Chandra does not have to be held immobile while exposing an image. Any blur is removed by repositioning each photon in software (using star positions from an 11.2 cm diameter optical telescope) at the Chandra X-ray Center

which operates Chandra for NASA from Cambridge, Massachusetts (USA). The ability to slice x-ray images at will is invaluable for analysis, e.g. to extract the spectrum of whatever looks interesting, without having to decide in advance. (The 'Proposers' Observatory Guide' has technical details on Chandra at http://asc.harvard.edu/.)

Chandra is in a high (10 000 km × 140 000 km) orbit. This makes any part of the sky observable without continual blocking by the Earth, increasing available observing time and allowing long uninterrupted observations for studying variable sources. Chandra cannot be reached with the Space Shuttle, so its survival depends on no critical system breaking or running out of supplies. Everything on board is set to last 15 yr or more. No plans exist to build another x-ray telescope with comparable resolution. Fortunately, NASA plans to operate Chandra for at least 10 yr.

Chandrasekhar, Subrahmanyan (1910–95)

Theoretical astrophysicist, born in Lahore, India, Nobel prizewinner (1983) 'for his theoretical studies of the physical processes of importance to the structure and evolution of the stars'. At Cambridge and Copenhagen he developed the theory of white dwarf stars, showing that quantum mechanical degeneracy pressure cannot stabilize a massive star, and that white dwarfs have a maximum mass (the *Chandrasekhar limit*). At the University of Chicago and Yerkes Observatory he investigated and wrote books on stellar structure and evolution, the dynamical properties of star clusters and galaxies, radiative transfer, hydrodynamic and hydromagnetic stability, the stability of ellipsoidal figures of equilibrium, and the mathematical theory of black holes. Like SIR JAMES JEANS, his work was characterized by an intense and protracted investigation of a certain area that appealed to him, which he then in retrospect presented in a definitive coherent book with order, form and structure. He edited the *Astrophysical Journal* for nearly 20 years. NASA's advanced x-ray astronomy facility satellite, AXAF, has been renamed Chandra.

Figure 1. A 4096 × 4096 pixel CCD with 15 micron pixels packaged for use in a large astronomical spectrograph.

Charge-coupled Device

Charge-coupled devices (CCDs) are silicon-based optical detectors used in most near-UV, visible and near-IR imaging and spectroscopic astronomical instruments. They range in format from television resolution (340 × 512 pixels) to 10 000 × 10 000 pixels. Modern CCDs have intrinsic noise of just a few electrons, dynamic range of 100 000 and quantum efficiency of over 90% throughout most of their useful operating wavelengths. These characteristics make CCDs the detector of choice for most visible astronomical detection requirements.

History and fundamentals

Boyle and Smith invented the CCD at Bell Labs in 1969. While originally intended as a memory device, CCDs have been most widely used as imaging detectors (see e.g. INFRARED ARRAYS, INFRARED IMAGERS, WIDEFIELD CCD IMAGERS). They were first used in astronomy in the late 1970s and rapidly replaced photographic film (see CAMERAS), photodiode arrays and photocathode-based detectors. A large format CCD is shown in figure 1.

The CCD basically consists of a one- or two-dimensional array of metal-oxide-semiconductor (MOS) capacitors in which the gate ('metal') of each capacitor is connected to buses to which external voltages are applied. These gates are actually made of polysilicon rather than metal to allow better light transmission through the frontside structure. Potential well minima are formed in the silicon under the CCD gates with the most positive applied voltage. Electrons are created from incident photons via the photoelectric effect and these photogenerated electrons are collected in the nearest potential well.

CCDs are sensitive to all wavelengths shorter than the cut-off wavelength $\lambda_{\rm cutoff}$ at which an incident photon's energy E is the same as the detection material's bandgap energy. All photons of shorter wavelength can excite an electron from the detector's valance band to its conduction band. For silicon, the most commonly used CCD fabrication material, $E_{\rm bandgap} = 1.12\,{\rm eV}$, so $\lambda_{\rm cutoff} = 1.1\,\mu{\rm m}$.

All gates that are electrically tied together are referred to as a phase. The majority of CCDs used in astronomy are three-phase devices, meaning that three electrical voltages must be applied to shift charge across the CCD. The distance from one phase to the next on the same bus defines the resolution of the detector, and is called a pixel. Typical CCD pixel sizes are 5–30 μm.

The most commonly used CCD in astronomy consists of a two-dimensional array of pixels. The image section of such a device can be viewed as an array of columns and rows of pixels with a single serial shift register at the end of the columns. Charge is shifted (or charge-coupled) one row at a time in all columns at once, shifting the last row into the serial register. The columns are defined by channel stops of highly doped material which confine charge from spreading between adjacent columns. In this manner no gates are required to define pixels on the horizontal direction in the imaging area. The serial register is itself clocked to sequentially shift charge to an output amplifier located at its end. External electronics and a computer are used to convert this analog output sequence of voltages into an image.

Architecture and operation

The operation of a CCD can be divided into three modes: clearing, integration, and readout.

Clearing is required to remove unwanted charge acquired by the device prior to making an integration. One method of clearing a device is to shift the charge from every pixel out of the device without recording the resultant data.

During integration, positive voltages are set on some phases to define potential minima where photoelectrons are collected. The positive voltage is applied to one or two of the three phases. At least one phase of each pixel must be more negative to create a barrier to charge spreading, without which the image would smear. It is possible for this barrier to be created by a fixed implant rather than an applied voltage. During integration, photoelectrons are collected but no shifting occurs.

A CCD must be cooled if the integration time is more than a few seconds to avoid the silicon's self-generated dark signal filling the potential wells. Most astronomical CCDs are cooled to about $-100\,^{\circ}$C in a liquid nitrogen dewar. Many smaller CCDs which are used for telescope guiding applications (where exposure times are just a few seconds) rely on thermoelectric coolers operating at about $-40\,^{\circ}$C to reduce dark signal.

After the integration time has expired, the CCD enters the readout phase. The location of each charge packet created during integration is shifted towards the output when a specific voltage sequence is applied to the buses, as shown in figure 2. Depending on architecture, split parallel clocks can be used to shift half the pixels toward one serial register and the other half toward another serial register, allowing readout in half the time. The serial register can also be split so that charge can be shifted toward amplifiers at each end, also decreasing readout time.

There are several common architectures of scientific CCDs. The entire area of a full frame device is used to

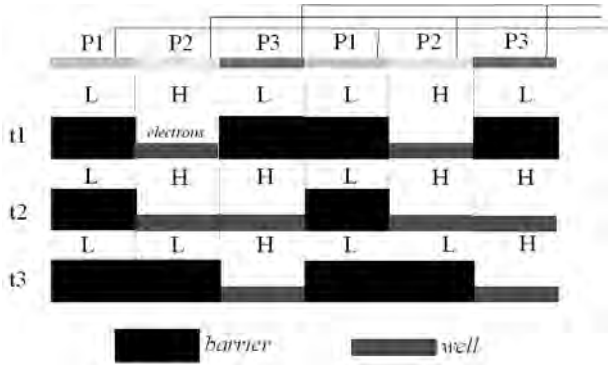

Figure 2. The pixel structure of a typical three-phase CCD showing the applied voltages, potentials, and charge packet locations at three separate times. The times are represented by t1, t2, and t3. Applied voltage is indicated by L (low) or H (high). The three-phases are represented as P1, P2, and P3.

collect images and is the most widely used in astronomy. A full frame CCD requires a shutter to open during integration (or exposure) and close during readout to avoid streaking from the light source while charge is shifted. In a frame transfer CCD, half of the imaging area is covered by an opaque frame-store mask. The unmasked section collects charge during integration. When the exposure is complete, the charge is very rapidly (10^{-6} to 10^{-4} s) shifted to the frame-store region where slower readout can take place while the next integration occurs in the image section. This eliminates the need for a mechanical shutter at the expense of losing half the detector's area for imaging. An interline transfer CCD is similar to a frame transfer device in that it has an opaque bus along each column into which charge can be rapidly shifted after each integration. Interline transfer devices are the most commonly used CCDs for high-light applications (such as TV video) but are seldom used in astronomical applications.

Amplifiers

When electrons are shifted to the end of a serial register they are next detected by the output amplifier. The gate of a transistor (usually a field effect transistor, or FET) is connected to a sense node onto which the charge is shifted from the last serial pixel. The charge appears as a voltage on the gate of the FET due to the capacitance of the node. The conversion factor is typically 1 to 10 μV per electron for modern amplifiers. The output voltage is buffered by the FET to create a measurable voltage across a load resistor located off-chip. This output voltage is easily amplified in the controller electronics and converted to a digital signal by an analog-to-digital converter. The node must be reset before sensing each pixel so that charge does not accumulate from pixel to pixel.

Read noise is a measure of the uncertainty in the output of the CCD and is often the dominant noise source for low-light-level imaging applications. Double correlated sampling (DCS) reduces the uncertainty in the absolute charge level of the node at each reset. Before shifting each pixel, the node is reset with an on-chip Reset FET. The output voltage is sampled and recorded, the pixel to be measured is then shifted onto the node, the node is sampled again, and the difference between the two samples is calculated and recorded as the actual pixel value. By using DCS and low-noise output FETs, read noise of less than two electrons can be achieved.

Quantum efficiency

The quantum efficiency (QE_λ) of a CCD is given by

$$QE_\lambda = (1 - R_\lambda) \exp(-\alpha_\lambda / t)$$

where R_λ is the reflectivity of the incident detector surface, α_λ is the absorption length of photons at the specified wavelength and t is the effective device thickness. Front illuminated CCDs have photons incident on the gate structure which absorbs almost all blue and UV light. These devices are therefore not useful for $\lambda < 400$ nm. In back illuminated (or thinned) CCDs, photons are incident on the backside of the device, opposite the gate structure. These devices must be very thin (<20 μm) for photoelectrons to be collected under the potential minima near the frontside gates. The thinning process is difficult and expensive, but QE is limited only by reflection at the back surface and the ability of silicon to absorb photons. Back illuminated devices can be antireflection coated to obtain peak QE of greater than 95% at specific wavelengths. The QE of CCDs drops significantly toward the near-IR because silicon's absorption length increases dramatically from 100 Å in the UV to 100 μm in the near-IR.

Chemical Compositions of Stars

In 1835, in a famously inaccurate forecast, the French philosopher Auguste Comte wrote of stars that, 'We understand the possibility of determining their shapes, their distances, their sizes and their movements; whereas we would never know how to study by any means their chemical composition . . .'. At the close of the 20th century the accurate measurement of the abundances of the chemical elements in the visible surface layers of stars of all classes has become a relatively straightforward astrophysical procedure. This is the result of several important developments: (1) a physically realistic theory of the structure of stellar atmospheres; (2) high-powered computer workstations which can efficiently integrate the equation of radiative transfer through a model stellar atmosphere; (3) advanced theoretical codes dealing with physically complex situations, such as departures from local thermodynamic equilibrium (LTE); (4) improvements in the basic atomic data needed to calculate the opacities which produce spectral absorption lines; (5) high-resolution spectrographs equipped with sensitive and linear electronic detectors; (6) access to the full range of wavelengths at which stars emit their light, including ultraviolet wavelengths observed from above the Earth's atmosphere.

The abundances of the chemical elements are a thread that ties together much of what we know about the evolution of stars, galaxies and the universe as a whole. The origin of the universe in the big bang yielded the most abundant of the elements, hydrogen (^{1}H) and helium (^{4}He), as well as small quantities of the isotopes ^{2}H (deuterium), ^{3}He and ^{7}Li. All the remaining elements and isotopes found in nature have been produced by the nuclear reactions that power the stars during the normal course of their evolution, or by rapid NUCLEOSYNTHESIS during the final cataclysmic explosions of certain stars as SUPERNOVAE or, for a few elements, by the spallation of heavier nuclei by COSMIC RAY particles in the interstellar medium. Some of the products of nuclear reactions occurring within a star are injected back into the interstellar medium as the star casts off most of its mass during the brief final stages of its evolution. There they provide the raw material for the formation of later generations of stars, planets and ultimately life itself.

This scenario for the origin of the elements leads to a profound consequence. The relative abundances of the elements are not necessarily constant in time or space. The initial chemical composition of a star is that of the interstellar cloud of gas and dust from which the star formed (see also INTERSTELLAR CHEMISTRY; COSMIC ABUNDANCE OF ELEMENTS). It is a function of the locality of the star's birth in the galaxy and of the age and state of evolution of the galaxy at the time the star formed. The composition of the observable surface layers of a star may be modified over time by processes occurring within the STELLAR INTERIOR. For example, nuclides created by reactions in the star's central core, or in shells surrounding the core, may be dredged up and intermixed with unprocessed material at the star's surface during the course of its evolution. Alternatively, the outer layers of an evolving star may be stripped away by mass loss, leaving its nuclear- processed interior exposed to view. Even in a young unevolved star atoms or ions of individual elements may settle below the observable surface under the pull of gravity or may be driven upward by radiation pressure and achieve high concentrations within the surface layers, if the atmosphere and envelope of the star are highly stable. Finally, a star may accrete processed material from a binary companion undergoing mass loss.

Overall, this is a wonderful complexity. It allows us to use the observed chemical compositions of stars as tracers of the record of evolution of our own and perhaps of other galaxies. It allows us to observe the outcome of processes occurring in the interiors of stars normally hidden from our view. Moreover, at least an approximate knowledge of the chemical composition of a star is needed to deduce the opacity and the mean molecular weight of its material, which are essential input parameters for the computation of theoretical models of its atmospheric and interior structure. Such models are used in turn to perform detailed compositional analyses and to predict other observed stellar properties. The consistency of these theoretical models with the observables they are used to predict—stellar luminosity and color, the detailed distribution of stellar flux with wavelength, spectral line strengths and shapes—gives confidence in or sometimes raises questions about our physical understanding.

How the chemical composition of a star is measured

Only the surface layers of a star are directly observable with an astronomical spectrograph mounted on a telescope. Therefore, the abundances of the chemical elements derived from spectroscopically dispersed starlight reveal only the composition of the star's atmosphere.

Our ability to measure a star's surface composition is enabled by the quantum structure of atoms and ions. Transitions of electrostatically bound electrons between quantum energy states, and the associated absorption or emission of photons, imprint on the stellar spectrum a pattern of discrete lines with wavelengths and relative strengths that are unique for every ionization state of every element in the periodic table. Accurate measurements of the wavelengths and relative strengths of spectral lines allow the identification of which chemical species are present. The measured absolute strengths of the lines—the amount of flux they have removed from or added to the background continuum of light emitted by the star—yield the abundances of those species. The atmospheres of cool stars also contain molecules (see STELLAR ATMOSPHERES: COOL STARS). The quantum structure of their electronic and vibrational energy states produces bands of closely spaced, discrete absorption or emission lines from which abundances can be measured.

While it is possible to measure abundances from emission lines (lines brighter than the continuum) produced in the hot, tenuous chromosphere or corona of a cool star such as the Sun, the simplest and most accurate determinations are obtained from the absorption lines arising in the denser stellar photosphere (the Fraunhofer spectrum). The reason lies in a set of simplifying assumptions which characterize the physical conditions within the photospheres of many stars rather well, enabling accurate computations of their structures and emitted spectra. These include (1) LTE (the local radiation field is coupled to the local gas kinetic temperature), (2) plane parallel geometry (the photosphere is very thin, compared with the radius of the star), (3) radiative equilibrium (energy is transported primarily by radiation) and (4) hydrostatic equilibrium (the photosphere is essentially motionless). In principle, violations of any of these assumptions can be treated with physically more complex theoretical computations. However, these will not necessarily be of greater reliability, if input physical parameters are inaccurate.

The observed depth of an absorption line centered at wavelength λ, at a position in the line's profile $\lambda + \Delta\lambda$, is a direct measure of the opacity of the stellar atmosphere produced by discrete electronic transitions within atoms or ions of the element in question, as they absorb photons of wavelength $\lambda + \Delta\lambda$. The chemical abundance of the element is derived by comparing the observed strengths and shapes of its spectral lines with a theoretical model of the emergent flux from the star, calculated by solving the equation of RADIATIVE TRANSFER through a model stellar atmosphere in the presence of this line opacity.

A theoretical model stellar atmosphere appropriate to a particular star provides a tabulation of the gas kinetic temperature, pressure and electron density at any depth x below the nominal 'surface' of the star. It is calculated with assumed abundances of hydrogen and helium and at least an approximate estimate of the abundances of heavier elements. From this information the total continuous opacity κ_λ at any wavelength, produced at depth x by the ionization of atoms or ions (bound–free electronic transitions), by molecular dissociation and by electron scattering can be derived. Radiation emerging from the star at all wavelengths is attenuated by these continuous opacity sources and both line and continuous opacity at any wavelength must be included in the calculation of emergent flux. In the absence of spectral lines, that flux is set entirely by the continuous opacity, and thus spectroscopists sometimes refer to the 'line-free continuum' as a reference flux level against which to measure the strength of a spectral line.

The line opacity is expressed in terms of a line absorption coefficient (units $\mathrm{cm}^2\ \mathrm{g}^{-1}$)

$$l_\lambda(x, \Delta\lambda) = \text{const} \times [n_{\mathrm{el},r,s}(x)/N_{\mathrm{el}}](N_{\mathrm{el}}/N_{\mathrm{H}})N_{\mathrm{H}} f \phi_\lambda(x, \Delta\lambda) \times (1 - \mathrm{e}^{-hc/\lambda kT}). \quad (1)$$

The factor $N_{\mathrm{el}}/N_{\mathrm{H}}$, the ratio of the total number of atoms and ions of the element per gram of stellar material to the number of atoms and ions of hydrogen per gram, is the key abundance parameter we seek to measure. It is allowed to vary freely in the calculations until they produce a good match to the observations. All other factors in equation (1) must be evaluated with care lest they corrupt the accuracy of the abundance measurement.

The factor $n_{\mathrm{el},r,s}(x)/N_{\mathrm{e}}$ is the population fraction of the element that lies in the excitation state s of ionization state r from which the line arises. In LTE this fraction is given by the combined Boltzmann and Saha equations. The assumption of LTE is a reasonable approximation of physical conditions in the deeper, denser layers of a stellar atmosphere where many weak and moderately strong spectral lines are formed. However, a more rigorous treatment of departures of energy level populations and ionization equilibria from their LTE values is sometimes required. The number of hydrogen atoms and ions per gram of stellar material, N_{H} in equation (1), follows directly from the abundance mix of hydrogen, helium and metals assumed in the original model atmosphere calculation.

The factor f is the transition probability, the likelihood that the atom will absorb or emit a photon between two particular energy states. It can be determined in the laboratory, for example by measuring the lifetime of the upper level of the transition, selectively populated by laser-induced excitation. This value is then combined with the measured fraction of downward transitions from the upper level that end up in the lower excitation state of the line in question (the branching fraction) to obtain the transition probability. The f value can also be calculated with semi-empirical codes that use the measured energy levels of the atom or from *ab initio* theoretical computations of the structure of the atom, using complex quantum mechanical programs. Systematic errors in f values are notorious as a major cause of errors in abundance measurements. Moreover, the lack of a comprehensive and accurate database of f values can thwart even the most sophisticated non-LTE computations of level populations.

The factor $1 - \mathrm{e}^{hc/\lambda kT}$ in equation (1) corrects for radiatively stimulated emission of photons in the line. Here h is the Planck constant, k is Boltzmann's constant, c is the velocity of light and T is the local gas kinetic temperature.

The function $\phi_\lambda(x, \Delta\lambda)$ in equation (1) describes the microscopic mechanisms which give the spectral line its finite width and shape under the conditions of temperature and density at depth x. These can affect the observed strength of the line (owing to saturation of the radiation available to be absorbed at wavelength $\lambda + \Delta\lambda$). Line broadening arises from a number of processes: (1) Doppler shifts resulting from thermal motion and small-scale turbulence of the gas; (2) the finite energy spread of the upper and lower states of the transition (a result of the Heisenberg uncertainty principle); (3) perturbations of the energy states due to the electrostatic fields of particles in the surrounding gas (Stark and van der Waals broadening); (4) shifting or splitting of the energy levels by magnetic fields (Zeeman

Dirac House, Temple Back, Bristol, BS1 6BE, UK

effect) or by nuclear effects (hyperfine splitting and isotope shifts). Macroscopic mechanisms which also alter the width and shape of the line, but without changing its total strength, include large-scale mass motions (turbulence, convection and mass loss) and stellar rotation. When spectral lines become very strong (highly saturated or black at their centers), they become less sensitive to abundance variations (curve-of-growth effect) and more sensitive in their strength to the function $\phi(x, \Delta\lambda)$. Thus, strong lines present significant challenges to the determination of accurate abundances.

Light emitted at depth x at an angle θ to the surface normal of the stellar atmosphere is attenuated along its path to the surface by a factor $\exp(-\tau_\lambda/\cos\theta)$, where the dimensionless optical depth τ_λ is given by

$$\tau_\lambda = \int_0^x (l_\lambda + \kappa_\lambda)\rho(x)\,\mathrm{d}x \qquad (2)$$

and $\rho(x)$ is the density of stellar material at depth x. The radiation emerges from a unit area of the stellar surface with intensity

$$I_\lambda(x=0,\theta) = \int_0^\infty S_\lambda(\tau_\lambda)\mathrm{e}^{-\tau_\lambda/\cos\theta}\,\mathrm{d}\tau_\lambda/\cos\theta. \qquad (3)$$

The function S_λ is called the 'source function' and is defined as the ratio of energy emitted per unit mass, time, wavelength and solid angle (the emission coefficient) at optical depth τ_λ to the total absorption coefficient $l_\lambda + \kappa_\lambda$. Qualitatively, equation (3) simply states that radiation emitted from greater depths in the atmosphere undergoes greater attenuation before it emerges at the star's surface. In LTE the source function is simply the Planck function describing black body emission at temperature T,

$$S_\lambda = B_\lambda(T) = (2hc^2/\lambda^5)(\mathrm{e}^{hc/\lambda kT} - 1)^{-1}. \qquad (4)$$

The Sun is the only star whose surface is seen as an extended disk which can be spectroscopically observed over the range of angles θ from its center ($\theta = 0^\circ$) to its limb ($\theta = 90^\circ$). Thus, equation (3) is directly applicable in modeling the observed intensity of sunlight at a particular point on the solar disk. For all other stars the relevant quantity is the integrated intensity over the hemisphere of the star facing toward Earth. What is observed at wavelength λ, in the spectrum of a star of radius R at distance d from the Earth, is the flux

$$f_\lambda = 2\pi(R^2/d^2)\int_0^\pi I_\lambda(0,\theta)\,\cos\theta\,\sin\theta\,\mathrm{d}\theta. \qquad (5)$$

The quantity $2\pi R^2/d^2$ may be treated as a scaling factor, which is a byproduct of fitting the observed flux to the integrated emitted intensity computed from a model stellar atmosphere.

Figure 1 gives an example of the process outlined above. Here, we have fitted the observed absorption line spectrum of a chemically peculiar B-type main-sequence star with a theoretically modeled synthetic spectrum in order to derive the abundance of the very heavy element thallium (atomic number 81). In this case the best fit to the spectrum is obtained assuming that thallium is in the form of isotopically pure ^{205}Tl, with an abundance of 4.66. By convention chemical abundances are expressed relative to hydrogen on a logarithmic scale, $\log(N_{\mathrm{el}}/N_{\mathrm{H}}) + 12$. In this star's atmosphere the abundance of thallium exceeds that in the sun by 3.76 in these logarithmic units, i.e. by a factor of $10^{3.76} \approx 5700$.

The Sun as a reference standard for chemical abundances

The abundances of the elements in the Sun and surrounding solar system are more extensively and reliably known than in any other star. Spectra of the SOLAR PHOTOSPHERE are observed with very high spectral resolution and signal-to-noise ratio because of the great brightness of the source, allowing the profiles of a multitude of weak or blended absorption lines to be accurately measured. Moreover, the structure and physical processes of the solar photosphere are well understood not only from theoretical models but also from empirical observations (e.g. the observed variations in the intensity of sunlight from the center to the limb of the solar disk). Photospheric SOLAR ABUNDANCES have been measured for approximately 60 chemical elements, and of these 43 are accurate to 25% or better—a small error bar, considering that the range of abundances spans 12 orders of magnitude.

For the Sun to serve as a useful baseline against which the photospheric abundances of other stars may be compared, it is important to establish (1) that the Sun's surface composition is essentially the same as the composition of the interstellar gas and dust from which it formed (i.e. that it has not been altered by processes endemic to the Sun itself) and (2) that the Sun's photospheric abundances are, at least on average, representative of other stars formed at about the same time in the same region of the Galaxy.

The composition of the solar photosphere is in close agreement with the composition of a rare class of meteorites, type CI carbonaceous CHONDRITES, for those elements for which accurate abundances have been measured in both, as summarized in table 1. The primary exceptions are Li, Be and B which are transported by convection into the solar interior and depleted by nuclear burning at relatively low temperatures. The meteoritic abundances can be measured accurately in the laboratory, providing an important calibration of the accuracy of astrophysical abundance measurements. For the small number of heavy elements for which substantial discrepancies exist between meteoritic and photospheric measurements, it is the photospheric abundances that are highly uncertain.

Radiometric dating of chondritic meteorites indicates that they are as old as the solar system itself (4.55 Gyr). The carbonaceous chondrites contain a relatively high

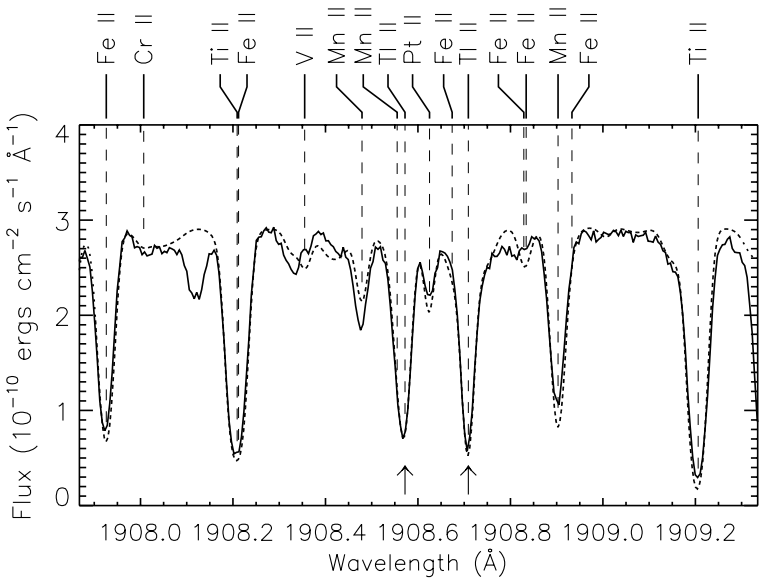

Figure 1. A small portion of the ultraviolet spectrum of the chemically peculiar star χ Lupi, observed with the Goddard High Resolution Spectrograph on board the Hubble Space Telescope (solid curve). Superimposed (dashed curve) is a theoretical spectrum in which the abundance of the thallium isotope ^{205}Tl has been adjusted to fit the two observed absorption lines of singly ionized thallium (Tl II) marked with arrows.

proportion of volatile elements and are believed to have been formed at great distance from the Sun. The close agreement between the composition of CI meteorites and the solar photosphere is strong evidence that the chemical composition of the Sun is (with a few exceptions) the same as that of the pre-solar nebula.

Precise measurements of the chemical compositions of main-sequence stars that bracket the Sun in spectral type (the Sun is type G2 V) indicate that the solar composition is typical for stars similar to the Sun in age, 'metallicity' (as indicated by their iron abundance) and distance of formation from the Galactic center. This is true at least for the dozen or so elements whose abundances have been measured from optical spectra in large statistical surveys.

The abundances of the elements in the solar system are often characterized as 'cosmic abundances' or 'normal abundances'. These terms are overly simplified. However, the solar system does provide a representative sampling of the abundances for a particular time and place in Galactic history, which with few exceptions remain unaltered by processes at work in the Sun itself.

Variations of abundances in time and space

The Galaxy is heavily populated with low-mass stars like the Sun. The theoretical lifetimes of such stars, from the zero-age main sequence to the tip of the red-giant branch, range from about 4.5 Gyr for an F5 dwarf of solar composition (1.3 solar masses) to about 29 Gyr for a K0 dwarf (0.8 solar masses). The Sun's lifetime is approximately 12 Gyr. Consequently, the ages of stars in this large and widely distributed population span the entire history of the Galaxy. Collectively their surface chemical compositions are an encyclopedia of Galactic evolution. In contrast the more massive O-, B- and A-type stars ($\geq$3 solar masses), which are hotter and shine more brightly, have short main-sequence lifetimes $\sim 10^6$–10^8 years. These young stars portray the *present-day* composition and state of evolution of Galactic material.

The composition of an individual star is dictated by the environment in which the star formed. This in turn is set by the history of stellar nucleosynthesis up to that time, by the processes which lead to the ejection of nuclides into the interstellar medium, by the relative amounts of time required for those processes to occur and by the dynamics of the Galaxy, which mixes and homogenizes interstellar material. Although a large variety of nuclear reaction chains occur in stellar interiors, there are only a few that ultimately lead to significant chemical enrichment of the interstellar medium.

There now exist plausible scenarios to explain the astrophysical production of essentially all the chemical elements, thanks to major advances in stellar evolution theory coupled with a large body of modern observational stellar spectroscopy. These are described in the following summary. It is a large step, however, from a plausible scenario to conclusive observational proof, and in some cases considerable work remains to be done.

The most abundant ISOTOPES of elements heavier than boron are thought to be produced primarily in one or more of the following sites: (1) type II supernovae (SNII), (2) type Ia supernovae (SNIa) and (3) highly evolved low- and intermediate-mass stars (1–7 solar masses). Type II supernovae are massive stars (>7–8 solar masses) that end their lives in titanic explosions. Type Ia supernovae are

Abundances are in the form $\log(N_{\rm el}/N_{\rm H}) + 12.00$, where N_i is the abundance by number of atoms per gram of material. Values in square brackets are best estimates from non-photospheric data (e.g. solar wind or corona). Values in parentheses are uncertain. Taken from Grevesse N, Noels A and Sauval A J 1996 Standard abundances *Cosmic Abundances (ASP Conf. Ser. 99)* pp 117–26, reproduced courtesy of the Astronomical Society of the Pacific Conference Series.

carbon–oxygen (CO) white dwarfs in close binary systems that explode in nuclear deflagration of carbon following mass transfer from or merger with the binary companion. The envelopes of low- and intermediate-mass stars are chemically enriched by an orderly sequence of interior nuclear processing during their lifetimes. These envelopes are shed as stellar winds and planetary nebulae as the stars evolve off the asymptotic giant branch (AGB).

The more massive AGB stars are believed to yield most of the carbon and nitrogen in the Galaxy. Oxygen and the 'α elements', whose most abundant isotopes are integral multiples of the helium nucleus (Mg, Si, S, Ar, Ca and Ti), are produced predominately by SNII. The 'odd-Z' light elements, Na and Al, evidently originate in the more massive and metal-rich SNII. Elements of the 'iron peak' (V, Cr, Mn, Fe, Co, Ni) come from both types of supernovae, but SNIa give a substantially higher yield of these elements.

Elements heavier than the iron peak arise from the successive capture of neutrons. In NUCLEAR PROCESSING during helium-shell thermal pulses in the interiors of low-mass (1–3 solar mass) AGB stars, neutron captures

occur steadily but infrequently, allowing time for beta decay of the neutron to occur before subsequent neutron captures. This is the 's- (slow) process'. S-process elements, whose most abundant isotopes are created by this process, include Sr, Y, Zr, Nb, Ba, La, Ce and Nd.

Explosive events such as supernovae are characterized by high neutron fluxes. 'R- (rapid) process' elements are created in such environments when the capture of neutrons occurs so rapidly that beta decay cannot take place prior to subsequent neutron captures. The sudden termination of neutron captures at the completion of the explosive event yields a pattern of abundances in the ejected material rich in beta-unstable high-neutron-number isotopes, which subsequently decay to more stable nuclides. As measured in the solar system, approximately 2/3 of the 49 stable elements heavier than Ge consist purely or predominantly of r-process isotopes. However, these are very-low-abundance, trace constituents of solar material. The pattern of *relative* abundances among the solar r-process elements appears nearly identical to that observed in very old, metal-poor stars in the halo of the Galaxy. This suggests that all r-process nuclides originate from a single site, most probably from SNII.

Figure 2 provides an example of how stellar chemical abundances are used to probe Galactic evolution. By convention, an abundance ratio given in square brackets is the logarithmic abundance value relative to the abundance in the solar system, $[A/B] = \log (N_A/N_B)_{star} - \log (N_A/N_B)_{sun}$. Between metallicity [Fe/H] $= -1$ and -4, corresponding to old stars in the Galactic halo, the measured abundance of α elements relative to iron exceeds the solar value on average by about +0.4 dex. There is a large star-to-star scatter which is partly real and partly measurement error. However, for the generally younger disk-population stars with metallicity [Fe/H] $= -1$ to 0 or higher, [α/Fe] drops steadily toward the solar value as metallicity increases. This pattern is interpreted as resulting from the time lag between the rapid evolution (<0.02 Gyr) of massive stars to become SNII and the much slower evolution (0.1–10 Gyr) of the progenitors of CO white dwarfs to become SNIa. The SNII produce high yields of the α elements and small amounts of iron. A burst of massive star formation early in the Galaxy's life would result soon thereafter in the ejection by SNIIs of material relatively rich in α elements into the interstellar medium, providing the raw material for the formation of low-metallicity, enhanced-α stars. In roughly a few hundred million years the first SNIa would have evolved from their 7–8 solar mass progenitors, yielding protostellar material significantly enriched in iron-peak elements, but with little additional production of the α elements. At this point the [α/Fe] ratio would begin to decrease, and this trend would continue as progressively lower-mass SNIa progenitors reached the endpoint of their evolution. This scenario is supported by stellar abundance measurements, such as those plotted in figure 2. The r-process elements follow a trend with [Fe/H] somewhat similar to the α elements. It is this evidence that suggests that SNII may also be responsible for their production.

In the innermost 7 kpc of the Galactic disk the oldest, most metal-deficient stars ([Fe/H] $= -1$ to -0.5) have larger enhancements of [α/H] than do their counterparts at larger distances from the Galactic center. Also, the enhancement of α-element abundances persists to higher values of metallicity in the stars closer to the Galactic center. This suggests that STAR FORMATION, particularly of massive stars that become SNII, probably began earlier and has proceeded at a greater rate in the inner part of the Galactic disk.

There is considerable evidence that the chemical composition of the Galactic disk has not evolved homogeneously. For example, it is very difficult to discern a clear relationship between [Fe/H] and stellar age in the solar neighborhood, although such a relationship would be expected from simple models of Galactic evolution. The youngest stars have [Fe/H] ~ 0 and the oldest have [Fe/H] ~ -1. However, there is a large and real scatter in metallicity at all ages in between. The natural variation in iron abundances among stars of the same age is estimated to be about $\pm$25–50% (1σ). The causes of this dispersion are not fully understood. It is clear that metal enrichment of the interstellar medium from which stars form is not only a function of time but of location. Important factors may include (1) local variations in initial mass function and star formation rates, (2) episodic infall of low-metallicity material (which can dilute the interstellar gas) onto localized regions of the disk and (3) the rate at which the Galactic disk becomes well mixed with gas recycled through stellar nucleosynthesis.

The stars of the Galactic halo are metal deficient, averaging about -1.6 in [Fe/H]. The current record for the most metal deficient star observed is held by the halo giant CD $-38\,245$ with [Fe/H] $= -4.01$. Intensive searches for zero-metallicity stars in the Galaxy have been unsuccessful. This suggests that the earliest epoch of nucleosynthesis may have occurred prior to the formation of the Galaxy itself, in protogalactic substructures.

The halo stars contain a significantly higher proportion of r-process elements than the Sun. For very old stars with low metallicity, [Fe/H] < -2.5, the dispersion from star to star in the abundances of r-process elements is much larger than for the presumably younger stars of higher metallicity. It is likely that the early chemical evolution of the halo was dominated by a relatively small number of SNIIs, with a wide range of yields of heavy elements. The composition of the halo interstellar material was very inhomogeneous early in the life of the Galaxy but became less so as time progressed and the ejecta of discrete SNII events became more thoroughly mixed.

Surface abundances as a window into the stellar interior

Stars spend most of their lives on the hydrogen-burning main sequence. In this phase the chemical composition of their surfaces, with few exceptions, offers no hint of

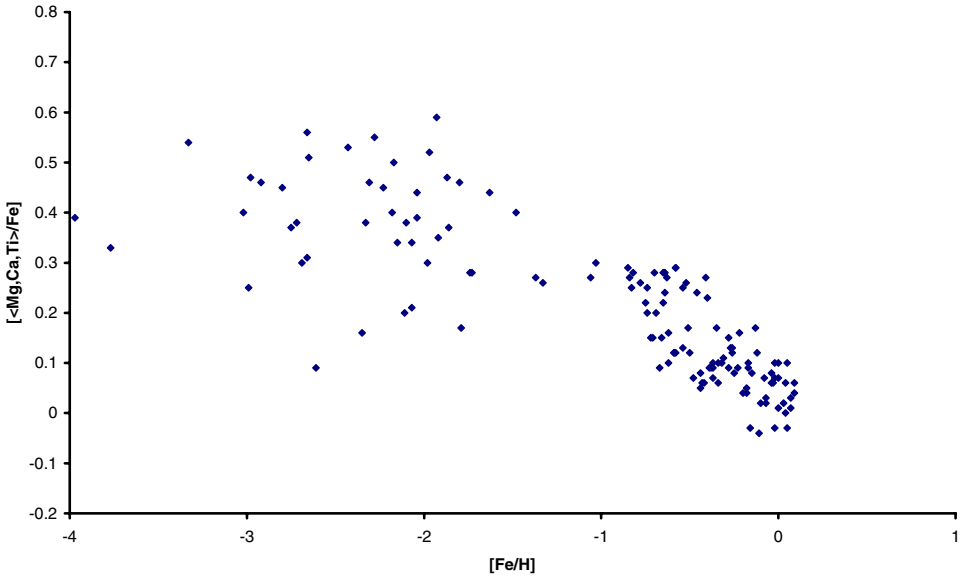

Figure 2. Each point represents, for an individual star, the average measured abundance of three 'α elements' (magnesium, calcium and titanium) relative to iron, plotted as a function of the measured abundance of iron itself. All abundances are in logarithmic units, relative to the Sun—the coordinates (0,0) correspond to solar abundances. Stars with [Fe/H] < -1 are found in the Galactic halo and those with [Fe/H] $\ll -1$ are extremely old. Stars with [Fe/H] > -1 are found in the disk of the Galaxy. The inflection near [Fe/H] $= -1$ is thought to represent the onset of major iron production in type Ia supernovae. (Data are taken from Nissen P E *et al* 1994 *Astron. Astrophys.* **285** 440–50, Edvardsson B *et al* 1993 *Astron. Astrophys.* **275** 101–52, Norris J E, Peterson R C and Beers T C 1993 *Astrophys. J.* **415** 797–810, Magain P 1989 *Astron. Astrophys.* **209** 211–25 and Gratton R G and Sneden C 1988 *Astron. Astrophys.* **204** 193–218.)

the nuclear transmutations taking place deep within their interiors. However, when a star exhausts the supply of hydrogen in its central core it undergoes relatively rapid and dynamic readjustments of its structure associated with the various phases of post-main-sequence evolution. The products of nuclear burning may then be dredged to the surface by convection (possibly assisted by rotationally induced circulation) or exposed to view by copious mass loss or both. Thus, the observed surface compositions of evolved stars provide important empirical underpinnings for the theory of STELLAR EVOLUTION.

Modifications of surface composition in this manner can take several forms: (1) changes in the relative abundances of carbon, nitrogen and oxygen and the carbon isotopes which mark the burning of H into He by the CNO cycle; (2) enhancements of the absolute abundance of carbon produced as a product of the 'triple-alpha' reaction which converts He to C; (3) enhancements of s-process elements created by the capture of neutrons released, for example, during the conversion by the 'alpha process' of ^{14}N into ^{25}Mg and of ^{13}C into ^{16}O; (4) depletion of hydrogen and enrichment of carbon, nitrogen, oxygen and s-process elements as mass loss strips away the hydrogen-rich stellar envelope. In a binary system mass transfer from a highly evolved star to a lower-mass companion can result in similar abundance modifications of the latter's atmosphere, which then displays abundance anomalies apparently at odds with its less-evolved state.

The terminology of spectral classification of evolved stars with 'anomalous' surface abundances (e.g. stars of types C, R, S, N, Ba, CH, HdC, RCrB, OBN, OBC, WN, WC, WO) is rooted in the history of observational stellar spectroscopy going back more than a century. It conveys no information about the progression of stellar evolution, as it is understood today, which has as its logical byproduct the development of these abundance 'anomalies'. This modern framework is well illustrated by the projected future course of evolution of the Sun. In broad outline the evolutionary scenario for the sun is similar to that of all stars up to about 7–8 solar masses. The major distinction among stars in this mass range relates to the manner in which they begin to burn helium into carbon in their central cores late in life—explosively in the case of stars less than about 2.5 solar masses, quiescently for the more massive stars.

After exhaustion of the Sun's central hydrogen fuel supply, its helium core will contract, hydrogen shell burning will commence, envelope expansion will occur and the Sun will evolve away from the main sequence and up the red-giant branch (RGB). In the initial stages of evolution up the RGB the Sun's convective envelope will extend deeply into the interior and, in this 'first dredge-up phase', will bring to the surface the products of CN nuclear processing which occurred while the Sun was on the main sequence. The solar photosphere will become enhanced in nitrogen and reduced in carbon, with a decrease of the ^{12}C/^{13}C ratio. Such changes are observed on the surfaces of metal-rich field stars like the Sun as they begin their ascent up the RGB in good agreement with the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

predictions of standard stellar evolution theory. Farther up the RGB, however, the Sun may exhibit additional abundance modifications of the same type, indicating dredge-up of CN-processed material from deep layers near the hydrogen-burning shell. Bright metal-poor RGB stars in GLOBULAR CLUSTERS can also show the products of ON-processing and proton-capture reactions at the stellar surface. Enhanced nitrogen, depleted oxygen, very low $^{12}C/^{13}C$ values (3–4), and abnormal abundances of sodium, aluminum and magnesium are all observed. For both metal-rich field RGB stars and bright metal-poor globular cluster RGB stars this extra mixing with deep interior regions is not predicted by basic theoretical models of the stellar interior. Standard models for these more evolved RGB stars contain an extended radiative region between the hydrogen-burning shell and the convective envelope that prevents the two from coming into contact. The resolution of this quandary is believed to reside in the influence of stellar rotation, which creates circulation currents capable of transporting CN- and ON-processed material upward to the base of the convection zone (see also STELLAR ROTATION ON THE MAIN SEQUENCE). This is a good example of the insight surface abundances can provide into otherwise undetectable processes hidden from view within the stellar interior. In general the observed surface abundances of RGB stars appear to depend in a complex (and often puzzling) manner on whether the stars are metal rich or metal poor, and whether they are found in globular clusters or in the field. 'Environmental pollution' from the ejecta of highly evolved stars in the near vicinity, particularly in the crowded stellar neighborhoods within globular clusters, is another process that is sometimes evoked to explain such complexities.

At the tip of the RGB, the Sun will achieve a high temperature in its degenerate central core, inducing 'helium-flash' ignition of the triple-alpha reaction that converts helium to carbon. The helium-burning core will join the outward-moving hydrogen-burning shell as the sources of the Sun's luminosity on the 'zero-age' horizontal branch. Subsequently, as the fuel supply of the helium core is depleted, the Sun will advance into a phase characterized by nuclear burning alternately within a helium shell and a hydrogen shell. During this 'two-shell' period its envelope will once again expand as it evolves up the AGB. Periodic thermal flashes associated with ignition of the helium shell will produce a plentiful supply of carbon and also of s-process elements, which will be dredged upward through the convective envelope to the surface. The Sun may first become an S star, with atmospheric enhancements primarily of s-process elements. At this stage its spectrum may even reveal technetium (^{99}Tc), a radioactive s-process element with such a short half-life (2×10^5 yr) that its presence essentially proves that nuclear-processed material has been dredged up from the deep interior very recently. In due course, farther up the AGB, the Sun will become a classical carbon or N-type star, whose spectrum is characterized by strong bands of CH, CN, C_2 and C_3. Ultimately, much of the Sun's hydrogen-rich envelope will be ejected as a PLANETARY NEBULA, leaving behind a WHITE DWARF core composed of carbon and oxygen, probably overlaid with thin surface strata of hydrogen on top of helium, segregated by gravitational settling. If the Sun had a less massive binary companion, its atmosphere could be polluted by the Sun's ejected envelope and acquire the anomalous abundances associated, for example, with barium (Ba) stars.

For stars more massive than about 7–8 solar masses, evolution induces surface abundance changes primarily as a result of large-scale mass loss in strong stellar winds. The WOLF–RAYET (WR) STARS are good examples. They are classified as a spectroscopic sequence: WN stars with enhanced nitrogen and helium, WC stars enhanced in carbon and WO stars enriched in oxygen. This ordering reflects progressively deeper exposure of the stellar core by mass loss, revealing the products first of hydrogen burning, then of helium burning and finally of carbon burning.

Atmospheric abundance anomalies in main-sequence stars

For a century stellar spectroscopists have been intrigued and bemused by the main-sequence stars classified as Ap ('p' denotes 'peculiar'), Bp, Am ('m' stands for 'metallic line'), Si, SrEuCr, HgMn or more generally CP (for 'chemically peculiar'). The atmospheres of these stars display astounding departures from solar abundances in many elements, including enhancements of heavy elements such as Hg by factors ranging up to 10^5–10^6. Large anomalies in the isotopic mixture of some elements are also occasionally observed (see, e.g., figure 1). There are no known nuclear processes capable of explaining these anomalies. The most important clue to their interpretation is the location of these stars in the HERTZSPRUNG–RUSSELL DIAGRAM. Collectively, they constitute 10–20% of all main-sequence stars with effective temperatures between approximately 9000 K and 16 000 K. Stars in this temperature range are too hot to possess extensive convective envelopes (the thin hydrogen convection zone dies out completely around 10 000 K) and too cool to have significant stellar winds. Many of them possess strong dipolar or quadrupolar magnetic fields. Both magnetic and non-magnetic CP stars tend to be intrinsically slow rotators. This combination of factors implies that the CP stars must possess hydrodynamically very stable atmospheres and envelopes. In such a quiescent environment atoms and ions are susceptible to gravitational settling and radiatively driven diffusion. The competition between gravity and radiation results in some ions drifting downward out of view below the photosphere, while others are being driven upward into the photosphere by radiation pressure transmitted through strong spectral lines or continua at wavelengths at which the star strongly emits flux.

This scenario is qualitatively supported by the observations. For example, the largest abundance enhancements often occur in elements that were originally

Copyright © Nature Publishing Group 2001

very low in abundance in the material from which the star formed (i.e. virtually all elements heavier than the iron peak), while the initially abundant elements (e.g. He, C, N) tend to be somewhat depleted. The abundant elements saturate the radiation field in their strongest spectral lines so that they absorb relatively little radiation pressure and (in the absence of any other material circulation or mixing) tend to sink. The converse is true of initially trace elements. Some ions (e.g. B II, Zn II) can absorb so much radiation pressure that they are blown entirely away from the star, presaging the onset of the stronger stellar winds at higher effective temperatures. Magnetic field lines also serve to guide the migration of ions under gravity and radiation pressure, producing surface abundance inhomogeneities or 'star spots' on the magnetic CP stars.

Radiatively driven diffusion and gravitational settling of atoms and ions have significance beyond the bizarre abundance patterns of CP stars. Theoretical diffusion models suggest that helium, second only to hydrogen in abundance, has been reduced in the Sun's photosphere by about 10% owing to gravitational settling. These processes may be at work deeper in the interiors of stars in regions of radiative equilibrium, modifying the opacity and mean molecular weight of stellar material.

The only other example of main-sequence stars which exhibit abundance anomalies in their atmospheres (excepting binaries that have accreted material from an evolved companion) is the very massive stars classified as OBN. There is evidence of CNO processing of material seen at the surface of these stars, i.e. enhanced nitrogen and reduced carbon abundances. Since these stars possess radiative envelopes, the most likely mechanism for transport of CNO-processed material from the deep interior is meridional circulation, which is a natural consequence of their normal, rapid rotation.

Chicxulub Basin

A terrestrial impact feature about 170 km in diameter centered near the coastal town of Puerto Chicxulub on the northern coast of Mexico's Yucatán Peninsula. The structure is well preserved but not apparent on the surface, being buried beneath about a kilometer of sediments. Its presence was suspected when arc-like formations showed up in plots of surface-gravity variations. Supporting evidence came in the form of microtektites (microscopic glass beads formed from impact-melted surface material) found in Haiti. Confirmation was provided by offshore drilling carried out in a search for new oilfields. The age of the Chicxulub basin is 65 million years, and its size is consistent with the impact of a 10 km diameter asteroid. Such an impact would have had catastrophic consequences for life and the environment. It seems likely that this was the event responsible for the mass extinctions that occurred at the end of the Cretaceous period 65 million years ago, leaving its mark as a sedimentary layer enriched in iridium at what is known to stratigraphists as the K/T boundary.

Chinese Astronomy

Astronomy has been a subject of interest to Chinese people since ancient times. As early as the sixteenth century BC, a supernova was recorded on an animal bone used in divination. In ancient China, the main mission for astronomers was to determine the farming seasons and to predict important events for the future according to the phenomena that appeared in the sky. In the minds of rulers in ancient times astronomy had been given special status among the disciplines of natural sciences because of the belief that it helps predict the future, and fate. As a result, astronomers had been appointed as royal officials since the twenty-fourth centre BC. A royal observatory was established in the West Zhou Dynasty (eleventh century BC–771 BC) and continued its existence into the beginning of the twentieth century.

Because in ancient times astronomy was serving the needs of rulers, it was treated as ASTROLOGY to some extent. for divination purposes, observation and predictions of solar and lunar eclipses were given special attention. The conjunctions of bright planets as well as appearances of comets, meteors and new stars were considered to have divinatory value. Therefore the movements of the Sun, Moon and planets, and rare astronomical phenomena were carefully and systematically observed. Thus a huge body of astronomical phenomena were recorded. The unique status of astronomy in ancient China guaranteed a separate astronomical chapter in the historical chronicle and more than 10 000 individual records of solar and lunar eclipses, sunspots, auroras, meteors and meteorites, comets, novae and supernovae, the occultation of planets by the moon and other phenomena were saved. An account of comets in the eleventh century BC and a record of sunspots in 28 BC are considered as the earliest recorded observations of these phenomena in astronomical history. China's records of historical supernovae are the most complete in the world. Among them, the recording of the 1054 supernova has been used to determine the age of the Crab pulsar. The records of eclipses have been applied to calculate the secular acceleration of the Earth's rotation (see also CHINESE ASTRONOMY IN HISTORY).

Astronomy enjoyed great development as a very important tool for making calendars and keeping time. Since the twenty-fourth century BC, a lunisolar calendar system, combining the lunar and solar calendars, was established and this system continues to exist even today in China. The length of a year is determined by the period of apparent motion of the Sun. The length of a month is determined by the synodic period of the Moon. The two calendar systems are coordinated by seven leap months in 19 years.

Since the seventh century BC gnomons were made to determine the time of the summer solstice and winter solstice, so as to determine the length of a year. The length of a year was taken to be 365.25 days in the calendar in use in the fifth century BC. In 1277, Guo Shoujing, a well known astronomer in the Yuan Dynasty, used a horizontal rod to replace the tablet in the gnomon and added a pinhole-imaging device to increase the sharpness of the shadow. The precision acquired by using the improved device resulted in an error of only about several arcseconds of the latitude of the Sun. The precise calculation of length of a year was recorded in a calendar book in 1199. According to this calendar, a year has exactly 365.2425 days. This calculation was confirmed by Guo Shoujing's observation in 1281. This is very close to today's value of the tropical year.

To keep time, a clepsydra (a water clock) was commonly used since the eighth century BC. A water-powered globe was built to show the revolution of celestial sphere by ZHANG HENG, the famous astronomer in the Han dynasty, in the third century. The water globe was improved by Yi Xing and Liang Lingzhan in the year 723, in which the escape wheel was invented. Yi Xing also deduced from his observations that the difference of altitude of the polar star was constant in a fixed distance along the terrestrial meridian. This knowledge was used by him to measure the size of the territory of the country.

From the second century BC to the thirteenth century AD, observatory instruments and observations improved dramatically. To determine the positions of stars and planets, an ARMILLARY SPHERE (an equatorial mounted instrument) was built in the first century BC. This instrument consisted of a polar axis, a sighting tube and, equatorial and horizontal circles with a scale of 365.25 degrees. In the fourth century BC, coordinates of 121 stars were listed in Shi Shen's star catalog. A more detailed catalog that included 283 constellations and 1464 stars had been compiled in the third century AD by Chen Zuo with China's own special constellations and naming system. However, even more remarkable was a star atlas that was stored in Dunhuang grottos, in which 1350 stars and 283 constellations were recorded early in the eighth century. Besides, as a result of detailed observations some laws were discovered. One of them was the discovery of precession by Yu Xi in 330. Careful observations in the fourth century also led to the discovery that comets' tails always point away from the Sun and that comets always reflect the Sun's rays.

Between the eighth century BC and the third century AD, different hypotheses regarding the definition and concept of the universe were actively debated and recorded. Among them, one hypothesis suggested that the Earth and stars float in an unlimited space. Theoretical thought—for instance, discussions on the structure of the universe—was considered to be useless to life and neglected in the Tang dynasty (618–906). Furthermore, people outside the royal observatory were forbidden to study astronomy from the Tang dynasty onwards. Unfortunately, therefore, the imperial management of astronomy restrained the free development of studies of astronomy in ancient China. Precise measurements of the position and movements of planets were not emphasized enough, except their synodic periods, and this absence of precision and the dominance of astrology in ancient China

resulted in much slower development of the theory of planetary motion than in Europe. Despite an abundance of many great astronomical discoveries, studies of those observations were not systematic and did not lead to many breakthroughs in astronomical theories. From the fourteenth to fifteenth centuries, the development of astronomy in China slowed down.

At the beginning of the seventeenth century, Mathoeus Ricci and other missionaries came to China from Europe and worked in cooperation with Chinese astronomers. They introduced modern western astronomy to China including the Copernican theory, telescopes and spherical astronomy.

Modern astronomy in China

In 1911, with the ending of China's last dynasty, the Qing Dynasty, the royal observatory was closed. The Chinese Republic later established the Central Observatory in Beijing. In 1958, BEIJING ASTRONOMICAL OBSERVATORY was rebuilt. Zo-Se Observatory was built near Shanghai in 1900, where a 40 cm refractor, the first large telescope used in astronomical study in China, was installed. Zi-Ka-Wei observatory, built in 1872, began to broadcast the time signal in 1914. These two observatories were combined to become the present SHANGHAI ASTRONOMICAL OBSERVATORY. In 1935, the PURPLE MOUNTAIN OBSERVATORY (PMO) was established as an institute of the Academy. Telescopes were installed one after another. In 1975, Yunnan Astronomical Observatory was separated from PMO to become an independent observatory. Shaanxi Observatory was built as the time service center of China in 1966. The majority of astronomers and instruments work in the five observatories managed by the Chinese Academy of Sciences.

The Beijing Astronomical Observatory (BAO) is engaged in astrophysical research including the abundance of the elements, short period ceiphids, supernova surveys and AGNs, starburst galaxies, optical identification of x-ray sources, large-scale structure of galaxies, narrow-band surveys, radio astronomy and solar physics. The optical, radio and solar observing sites are separately located in Xinglong, Miyun and Huairou along the Great Wall. The BAO manages the Beijing Regional Warning Center of the International Space Environment Service. The solar magnetic field of active regions and solar radio eruptions are monitored. Predictions of events of solar activity are provided. A 2.16 m telescope, solar magnetic field telescope, 1.26 m infrared telescope, and meter-wave radio synthesis telescope are installed in BAO. World Data Center-D for Astronomy is also located at the BAO.

The Shanghai Astronomical Observatory (SAO) focuses more on studies of astro-geodynamics and astrometry. VLBI measurements, satellite and lunar laser ranging are used to determine Earth rotation parameters. The variability of the baseline is being interferometrically measured in cooperation with Japanese, German and American observatories. They are also beginning to develop some astrophysical studies in SAO. Open cluster variables in spherical clusters and N-body simulations are the main areas of interest in astrophysical research. Two 25 m radio dishes have been installed in Shanghai and Urumqi stations and are working as VLBI units of EVN. A 1.56 m reflector is operated in SAO. The Eastern Asia–Pacific Space Geodynamics Network was established in SAO in 1994, in which more than 20 VLBI, GPS and SLR stations of about 10 countries participate.

Scientists at the Purple Mountain Observatory (PMO) conduct research on the solar system, molecular astronomy and satellite dynamics. Minor planets, planetary physics, artificial satellite dynamics and astronomical almanacs are traditional research fields. Researches and techniques in millimeter wave astronomy have made tremendous progress in recent years. A 13.6 m mm-wave telescope has been installed in the Qinghai plateau.

The fine structure of the Sun, rotation of stars, close binaries, stellar structure and BL Lac objects are the main fields of research in Yunnan Astronomical Observatory. Scientists here are conducting research into artificial satellite dynamics, astrometry and solar radio eruption. A 1 m telescope and several small telescopes are in use in Kunming, the capital of Yunnan province.

Institutions providing astronomical education report to the Ministry of Education. These institutions include: the Department of Astronomy of Nanjing University, the Department of Astronomy of Beijing Normal University and the Department of Astrophysics of Peking University. Though no observation facilities are available in these universities, scientists and faculties from these universities can use telescopes and observations from different observatories based on the quality of the applications.

The High Energy Astrophysics Center of the Institute for High Energy Physics, the Center for Astrophysics of China Science and Technology University, astrophysics groups in Nanjing Normal University, Jiaotong University and Huazhong Normal University are active in researches on high-energy astrophysics and plasma astrophysics.

In Teipei, the Institute for Astrophysics of the Academia Sinica was built in 1990. This institute adds two dishes to the Sub-Millimeter Array (SMA) and supports and shares 10% of BIMA to cooperate with astronomers in the US. The Institute for Astronomy was established in the Central University at Zhongli, a town south of Teipei; its 70 cm telescope was installed in Mount Yu. A solar oscillation net with five detectors installed in Big Bear, the Canary Islands, Tashkent, Beijing and Teipei has operated in Tsinghua University since 1991. In Hong Kong, astrophysics research groups are actively working in Hong Kong University, Hong Kong Chinese University and Hong Kong Science and Technology University.

The Beijing Planetarium was established as a center for popular astronomy in 1957. The Astronomical Museum in Taipei was built in 1996, in which the exhibition area covered 50 000 m^2. Hong Kong Planetarium was built in 1980. More than 50 small planetaria are scattered across the country.

The CHINESE ASTRONOMICAL SOCIETY (CAS) is a non-government organization for astronomers and scientists. The CAS is an affiliate of the INTERNATIONAL ASTRONOMICAL UNION (IAU). The Astronomical Association, located in Teipei, is an affiliate of the IAU. The Hong Kong Astrophysics Society was established in 1997.

Most of the telescopes used in the observatories of the mainland are made by the Center for Research and Manufacture of Astronomical Instruments in Nanjing in cooperation with the observatories. New initiatives for future astronomical instruments in China have been scheduled. The Large Multi-Object Spectroscopy Telescope (LAMOST) was approved as a national project in the 1990s. LAMOST is an alt-azimuthally mounted reflecting Schmidt telescope. The optical system consists of a 6×6.7 m spherical mirror fixed on the foundation and facing north. An aspheric reflecting mirror lies at the center of the sphere 40 m away. Spherical aberration will be eliminated in real time with the help of active optics. The effective aperture is 4 m. The focal length is 20 m. The field of view is about 5° giving a linear diameter 1.75 m. Due to the large FOV, about 4000 fibers can be attached to the focal surface so the spectra of 4000 objects can be simultaneously observed. The LAMOST project will be completed in 2004.

Financial support for astronomy in China comes mainly from CAS, the Ministry of Education, the Ministry of Science and Technology, the National Natural Sciences Foundation (NNSF) and the National Planning Committee. The CAS and the Ministry of Education provide operational expenses for their affiliate observatories and departments, which amount to US$10 million per year approximately. NNSF supports individuals and groups as well as moderate and small programs of about US$1 million per year. The National Planning Committee supports large projects involving the construction of large scientific instruments. The budget of LAMOST is US$30 million. The Ministry of Sciences and Technology funds the larger research projects, which have budgets of about US$1 million a year.

Chinese Astronomy in History

This article outlines knowledge of the sky and the celestial motions that originated in Chinese culture from earliest times to 1912, when the use of traditional techniques ended along with the Chinese empire.

The Chinese experience of astronomy for the past two thousand years repays study because, unlike Europe, the level of knowledge and practice remained high without interruption for more than two thousand years and because it was based on styles of work quite different from those prevalent in the West.

Setting

All of the great historical civilizations have exchanged ideas and artifacts since the New Stone Age. China was so isolated from Europe, the Middle East and India that outside scientific influence remained controllable until the mid-19th century. It remained a centrally ruled empire larger than all of Europe for more than 2000 yr. Even in brief periods of division, the continuity of its high culture, unlike that of Europe for much of the Middle Ages, was never interrupted.

Despite China's enormous extent and local diversity, its literate elite, because of their classical educations, shared not only a language but values and patterns of thought. Among these values was overwhelming prestige for the civil service. One generation of talented astronomers after another sought the only employer ready to provide large, long-term investment in scientific research and development.

The government supported large-scale astronomical projects, from the 2nd century BC on, because of the ideology that justified its power. It claimed that the imperial house was chosen by Heaven (that is, the divine order of nature) to shape society in its image. The monarch's personal virtue and charisma, not his managerial skills, kept him in touch with the cosmic order and enabled him to keep the state in harmony with it.

This doctrine included the notion of the Mandate of Heaven. Heaven chose an exceptionally virtuous family to rule. When eventually its descendants no longer maintained that virtue, Heaven transferred the mandate to a worthier family. The conquest that ended a dynasty and began a new one was thus not a crime—if it succeeded.

There was an early warning system. Certain anomalous phenomena in the sky (or, less often, on Earth) signaled that the ruler must reform or be dethroned. Auspicious omens acknowledged a sage reign—or, in different circumstances, encouraged a sage rebel.

Prompt notification was essential. As a result, the imperial court included an amply staffed Bureau of Astronomy. Its responsibilities for ASTROLOGY and mathematical astronomy were intimately related. Its officials scrutinized the sky for omens, recorded them, determined their meaning from the Bureau's archives and reported them so that the emperor and his officials could determine how to respond. Accounts of this process suggest that astrology was important not as a source of objective predictions, right or wrong, but as a ritual form for the open discussion of policy.

Equally important was moving as many phenomena as possible from the realm of the ominous to that of the predictable, an effort that improved computation. For instance, by the late 3rd century AD new moons on the last day of the month had ceased to be omens. Because it was impossible to consistently forecast solar ECLIPSES that would be visible from a given observatory, unpredicted eclipses remained the chief concern of rulers.

The emperor symbolically expressed his control over time as well as space by issuing the annual CALENDAR (actually an ephemeris or almanac that included eclipses and planetary phenomena). He expected the Bureau to incorporate in it the most accurate predictions possible, particularly those of eclipses.

As a result of this ongoing state sponsorship, the published historical record offers unbroken, dated records of most important celestial phenomena, and detailed accounts of the evolving methods used to make EPHEMERIDES, for more than two millennia.

Beginnings

Records written on bone in the 15th century BC include observations of phenomena in the sky. Because these documents come from royal archives, eclipse sightings are prominent and figure as portents. They are dated using a cycle of 60 days, uninterrupted until modern times.

In the 4th and 3rd centuries the warring states used a variety of discrepant calendars. All were based on the tropical year and the lunation. They were generated by counting from an epoch chosen as the beginning of a year, month, 60 day cycle and day. The astronomical year began at the winter solstice, the month at the new Moon—not an observable event—and the day at midnight. Thus the epoch of the Triple Concordance system of 7 BC was exactly set at midnight of sexagenary day 1, 143 127 yr before the winter solstice of 24 December 105 BC.

Since the civil year needed an integral number of days per month and months per year, months of 29 or 30 days roughly alternated, so that a civil year of 12 months would be 354 or 355 days long. Chinese adopted intercalation, at first using what is known in the West as the METONIC CYCLE. They added 7 extra months every 19 yr. That schema spaced intercalary years of 383 or 384 days equally to yield a long-term average of $365\frac{1}{4}$ days per year. Over the centuries, more elaborate schemes of intercalation, and then computation of true lunations, yielded a mean tropical year that by the 13th century AD was 365.2425 days.

Observations

The first clearly instrumental observations measured the shadow cast by an upright gnomon higher than a human. They cannot be dated certainly before the 4th century BC. The longest shadow of the day determined the moment of noon and the north–south direction. Once astronomers

noticed that the noon shadow varied in length from day to day, it became possible to define the beginning of the year as the day of the longest noon shadow, the winter solstice. At night, sighting along a north–south line on stars passing the gnomon yielded their meridian transits, which were important before the invention of graduated instruments.

The development of graduated armillary instruments with a sighting tube is a vexed topic. The earliest known document that requires the use of a simple dioptra is the *Gan Shi xing jing* (Star canons of Gan De and Shi Shen), the data in which have been dated by error analysis at ca 70 BC. Geng Shouchang used a simple equatorial armillary in 52 BC; an ecliptic ring was added by AD 84 and horizon and meridian rings by 125.

Chinese degree measurement was not derived from the Babylonian sexagesimal system. It was based on the *du*, originally a measure of time intervals between meridian transits, but after about AD 180 redefined as the distance of one day's mean solar travel. There were initially $365\frac{1}{4}$ *du* in a circle, and the number changed with the value for year length. The precision of the first star catalogue was 1/8 *du*; this increased to 0.05 *du* by AD 1279.

The coordinates of observation, as in modern astronomy but unlike those of Europe before the Renaissance, were equatorial, measured from the winter solstice point rather than from the Sun's position at the spring equinox. There is little to choose between the two systems, since the Sun, Moon and planets orbit close to the ecliptic, and the stars rotate parallel to the equator. It was necessary in either case to convert positions along one to positions along the other. Early Chinese accomplished this with simple numerical methods; by the reform of 1279, gradual moves in the direction of spherical trigonometry greatly increased accuracy.

The time of observations was generally measured by water clocks, of which several examples survive from the last two centuries BC. The precision of records was at first ca 1/2 h. Despite great elaboration over the centuries, typical precision by 1300 was perhaps 0.4 h, and significantly better for solar eclipse data.

Coordinates of celestial objects were, as in Europe, measured from markpoints spaced closely enough that observers without instruments could estimate with fair accuracy the distance of objects from them in *du*. Unlike the 12 houses of the zodiac, the Chinese *xiu* (lunar lodges) were a set of 28 unequally spaced stars in prominent constellations. This was similar to the coordinates used in India and called *nakshatra* and those of the Islamic world called *al-manāzil* (see INDIAN ASTRONOMY, ISLAMIC ASTRONOMY). The lunar lodges were in principle as satisfactory as the zodiac, but occasional unintended changes in their determinative stars affected accuracy when new predictive methods were tested against ancient observational records.

Endless polemics have failed to settle where and when the lodges originated. Their 28 names first appear together on a lacquer box buried in 433 BC. Only in sources of the 4th or 3rd century do they record coordinates of observations.

Calendar reforms

The first unification of China, in 221 BC, led to a single calendar, but after a century the system was regularly a day off in predicting new moons. After a reform of the calendar in 104 BC, in 7 BC astronomers expanded the calendar-making techniques into an astronomical system (*li*) that included all predictable phenomena, including eclipses and planetary motions. This expansion was motivated as much by two emperors' desire to renew their political order along lines determined by cosmic religion as by a drive toward technical innovation.

The Triple Concordance system of 7 BC was not revised piecemeal but replaced by a complete new computational system in AD 85. Because integral replacement became the norm, and imperial prestige depended on accurate prediction, 101 systems were proposed before 1912, of which 41 saw official use.

Like Ptolemy's *Almagest*, this Triple Concordance system set out step-by-step procedures for generating the complete ephemeris mentioned above. A clerk with only basic arithmetical skills could carry out the entire process, consulting a built-in table that obviated a complex computation.

Chinese computational methods differed from those of the Greeks in their numerical or algorithmic, rather than geometric, approach. Predicting solar eclipses, which amounts to finding the intersection of a shadow cone with a spherical Sun, is difficult without geometry. That is why it remained a central problem.

Chinese began by counting off mean solar and lunar cycles to find when the two bodies intersected. The results were so poor that astronomers apparently counted off 135 months from an observed eclipse to predict another one, a more successful technique. However, the point of mathematical astronomy was predicting without having to look at the sky. Yang Wei in AD 237 did away with reliance on prior observations by introducing the concept of eclipse limit (in modern terms, the distance of the conjunction from the intersection of the orbits). Techniques for computing apparent rather than mean lunar (AD 223) and solar (ca. 604) motions, and their combination in predicting lunations (619), were extremely important. Elaborate linear interpolation algorithms (fifth order by 1064) and prototrigonometric methods (beginning at about the same time) increasingly approximated the results of geometric analysis.

Development

The bureaucratic character of astronomy did not change markedly over the centuries. Because appointments tended to be sinecures, often hereditary, innovation often came from outsiders—amateur astronomers who had access to information about previous systems published in the dynastic histories. The originator of a new system, after it was thoroughly tested, was often appointed to the Bureau. Some security-minded dynasties forbade the private study of astronomy, cutting off this source of new methods. However, other administrations tested

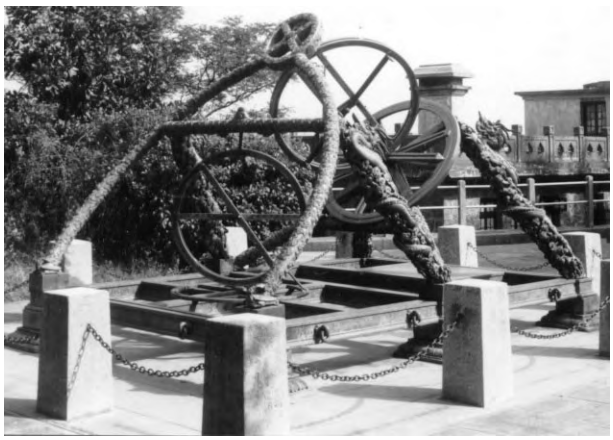

Figure 1. Abridged armillary of ca 1270, now at Purple Mountain Observatory, Nanjing.

officials to raise the level of practice or included technical questions on the general civil service examination to motivate widespread study of astronomy.

Since the government valued astronomical knowledge, and remained the only source of massive support for research, its large projects took the science in several new directions. These included the following

- Observatories were built with a large array of instruments. The huge observational ARMILLARY SPHERE of 1442, reproducing a design of 1074, and the 'abridged armillary' (equatorial torquetrum, *jianyi*), the design of which goes back at least to ca 1270, survive (figure 1).
- Elaborate demonstrational instruments, such as a series of water-driven, escapement-controlled astronomical clocks were constructed. Their high point was the enormous clock that Su Song built ca 1090 (figure 2).
- Large-scale surveys of longitude and latitude were carried out to increase accuracy of data recording and to investigate such matters as the differing visibility of eclipses. That of 1279 covered 6000 miles north–south and 2000 miles east–west.
- Fixed stars were repeatedly catalogued, especially to fix the determinative stars of the lunar lodges. Ten such surveys became the basis of official astronomy between 964 and 1106 (figure 3).

Despite the conservatism inherent in the official focus and stereotyped form of astronomy, the government facilitated improvements in every aspect of the ephemeris. A few important ones not already noted are (in order of the date at which official use began, or otherwise that of writing):

- Precession (literally 'annual difference', *sui cha*, 330), defined as the time difference between the tropical and sidereal year. This constant corresponded to a shift of the winter solstice point 1 *du* per 50 yr. Chinese did not see it as a rotation of the equatorial about the ecliptic pole.
- Exact times of new moons were determined from observations of lunar eclipses (384).
- Sustained investigation of apparent planetary motions was carried out (roughly 729 on). Originally the emphasis on eclipse prediction led to neglect of this problem.
- An approximation to spherical trigonometry applied to the celestial sphere (1279) was combined with a cluster of other changes, such as substituting decimal parts for mixed fractions and discarding the traditional dependence on counting off cycles from an early epoch.

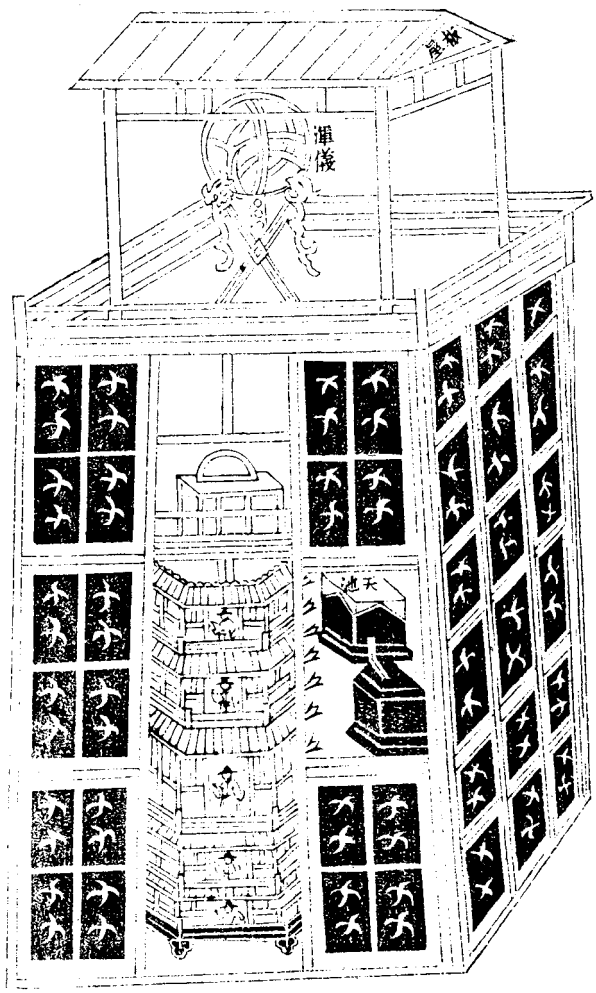

Figure 2. The great astronomical clock of 1089, from the contemporary *Xin yixiang fa yao*.

After the revolution of 1911, the traditional approach was discarded, not because of its particular shortcomings but because of a blanket move toward modernization. After over a century of imperialism and incessant war,

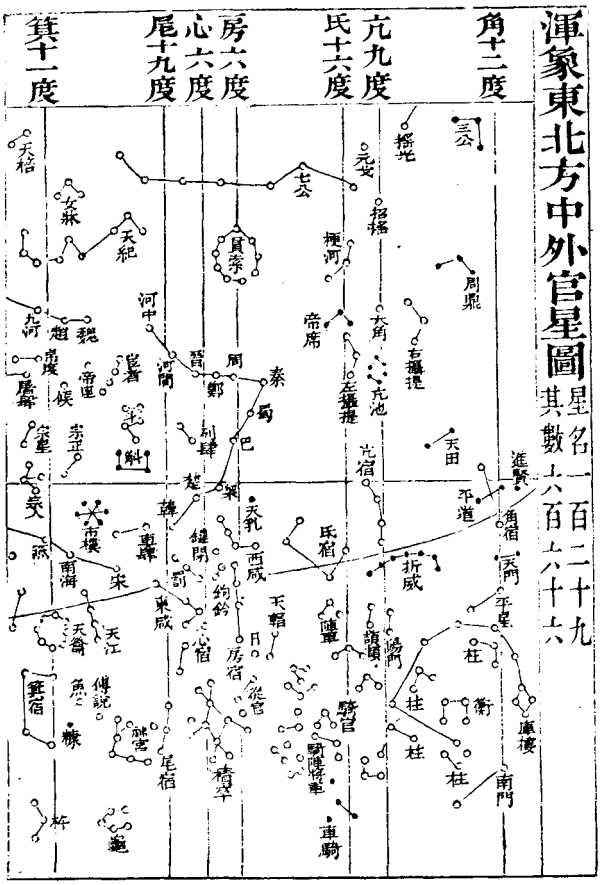

Figure 3. Part of a star map of the late 11th century, from *Xin yixiang fa yao*.

China was too poor to invest massively in modern astronomy at something approaching the world level until after 1975 (see CHINESE ASTRONOMY).

International influence

Since China was the predominant culture in East Asia, the institutions and methods of its official astronomy provided a foundation for counterparts (always with local character) in Korea, Japan and Vietnam.

The desire for accurate prediction of solar eclipses motivated Chinese to hire experts in the geometric methods of the Greek tradition. They employed Indians from 665 on, Muslims during the Mongol occupation (1279–1367) and Jesuit missionaries in the 17th and 18th centuries. The latter, in fact, by offering the Manchu invaders their skills at casting cannon and computing the mandatory imperial ephemerides, took control of the Astronomical Bureau. Even when the Jesuits introduced European techniques, they remolded them into the traditional form of the *li*. Although they mentioned Copernicus and other important European figures in their Chinese writings, the constraints of the Counter-Reformation prevented them from describing revolutionary changes in cosmology.

Applications in modern astronomy

Although narrow-minded positivists ignore the history of astrology, in China the main legacy of traditional to modern science has come not from computational techniques but from detailed astrological records of observations, unequalled elsewhere. The fullest ancient supernova data that have been correlated with pulsar phenomena are generally Chinese. Information on the time, magnitude, and duration of large numbers of solar and lunar eclipses has cast light on the secular acceleration of the Moon and Earth. Dates of every return of Halley's comet for over 2000 yr have clarified its motion. Records, some multiple, on 147 distinct appearances of sunspots and of about twice that many auroras have proved valuable for investigating the relations between the two phenomena and testing hypotheses about sunspot minima.

Chiron

Chiron is among the present-day population of minor planets called CENTAURS, whose orbits cross those of the giant outer planets Saturn, Uranus and Neptune. Chiron was the first Centaur discovered, and perhaps is the most unusual due to its cometary activity and other characteristics. Centaurs are probably former residents of the KUIPER BELT, and so Chiron may be considered our first and most accessible emissary from the far reaches of the outer solar system. Studies of Chiron and other Centaurs and Kuiper Belt objects allow us to probe the formation and evolutionary history of the solar system.

Chiron orbits the Sun between Saturn and Uranus on a 50-year orbit, ranging in heliocentric distance from 8.5 AU to just under 19 AU (an AU, or astronomical unit, is the distance between the Earth and the Sun, and is roughly equal to 1.5×10^{13} cm). The specific orbital properties of Chiron are given in table 1. Chiron passed perihelion on 14 February 1996, and was the focus of an international observation campaign at that time.

Table 1. Orbital properties of Chiron.

Period	50.2 years
Eccentricity	0.38
Inclination	6.94°
Perihelion distance	8.443 AU
Aphelion distance	18.765 AU
Semimajor axis	13.633 AU
Argument of perihelion	339.1°
Longitude of ascending node	209.4°

Chiron's diameter is about 180 km; the range of recent measurements taken at various wavelengths is about 150 to 370 km, though occultation and IR observations support the value near 180 km. Chiron has an absolute magnitude of $H = 6.5$ mag; over the range of its orbit, its apparent magnitude varies from 16 to 20 mag. The visible lightcurve is comparable to that in the ultraviolet, with a period of 5.9 h and a peak-to-peak variation of about 0.1 mag.

Measurements at visible wavelengths have shown that Chiron typically has a comparatively neutral, or gray, color (meaning that it does not preferentially reflect or absorb particular wavelengths of light that illuminate it). This gray color is independent of rotational phase, though there have been observations showing some color changes possibly connected to its cometary activity. For example, ultraviolet observations show a similar neutral color during quiescent periods, though during an outburst, Chiron exhibited a possible blue color slope and the ALBEDO (reflectivity) increased.

Some key physical properties of Chiron are given in table 2. The significant digits given in these values are roughly indicative of their uncertainties.

The discovery of Chiron follows an historical progression of discovering new classes of minor planets in regions of the solar system previously thought to be empty. The first asteroid, CERES, was discovered by Piazzi in 1801,

Table 2. Physical properties of Chiron.

Diameter	~180 km
Synodic rotation period	5.91783 h
Lightcurve amplitude	7–10%
Absolute magnitude	6.5
$B - V$ color	0.70
Asteroid spectral type	C
Visual geometric albedo	0.05
Ultraviolet geometric albedo	0.08
Magnitude slope parameter	0.15

and was soon followed by discoveries of PALLAS, JUNO and VESTA over the next six years. As telescopes, detectors and techniques improved, the observational limits of the asteroidal bodies progressed with time from the main belt, moving both outward (through the Cybele, Hilda and TROJAN ASTEROID groups) and inward (through Amor, Apollo and Aten groups).

In 1977 the horizon of the small bodies in our solar system was extended to orbits as distant as Uranus, with the discovery by Charles Kowal of object 1977 UB, later designated as asteroid number 2060, and named Chiron. Chiron implied a new class of small bodies called Centaurs—outer planet crossers. A total of 17 Centaurs had been discovered as of the end of 1999. Fifteen years after the discovery of Chiron, our view of the solar system was expanded further by the first discovery of a Kuiper Belt object, 1992 QB_1, by David Jewitt and Jane Luu. This was the first of hundreds of such objects that now have been found to have orbits beyond Neptune. These observational discoveries convincingly established that the vast outer planet and trans-Neptunian regions are, indeed, teeming with small bodies.

Chiron's connection to the rest of the solar system

Chiron is believed to be an escapee from the Kuiper Belt, a reservoir of COMETS and larger PLANETESIMALS postulated by Edgeworth and Kuiper in the 1940s and 1950s. One primary line of evidence for this origin of Chiron is dynamical. Studies by Shio Oikawa and Edgar Everhart, and more recently by Luke Dones, Harold Levison and Martin Duncan, have shown that Chiron's orbit is unstable due to perturbations by the giant planets on timescales of $<10^6$ years. This, and Chiron's comet-like activity (discussed in the next section), provide strong, yet circumstantial, evidence that Chiron is a recent addition to the planetary region.

Around the same time as the dynamical instability of Chiron's orbit was discovered, orbital evolution simulations first began to provide convincing support for the idea that orbits for most of the short-period comets could not be derived from a distant, spherical OORT CLOUD. As discussed by Martin Duncan, Thomas Quinn and Scott Tremaine in papers in 1988 and 1990, a postulated disk source in the outer solar system (the as-of-yet undiscovered Kuiper Belt) must be the source of such objects. Dynamical simulations have shown that objects in

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the Kuiper Belt between 30 and 50 AU exhibit dynamically chaotic orbits due to gravitational perturbations by the giant planets. As such perturbations occur, the perihelion distances of an object in this region can rapidly decrease so that the object's orbit eventually crosses Neptune's orbit. Once this occurs, the object will almost certainly experience a close encounter with Neptune, which then can throw the object into either a much larger or much smaller orbit. Those objects that are thrown into smaller orbits can then be influenced by strong perturbations by the other giant planets. In this way, objects in the Kuiper Belt can successively evolve into orbits like those of the short-period comets and of the Centaurs, like Chiron.

Additional evidence that Chiron came from the Kuiper Belt is physical. Chiron's diameter of approximately 180 km, its color and the indications of volatiles on its surface are consistent with the size estimates, observed colors and expected surface chemistry for some types of Kuiper Belt objects.

Given the dynamical instabilities of Centaur orbits, the plausible method for moving Kuiper Belt objects into the solar system, and the physical similarities between Centaurs and Kuiper Belt objects, it is therefore likely that Chiron and the other Centaurs are unique transition objects, connecting the outer solar system's Kuiper Belt and inner solar system objects such as Jupiter family comets.

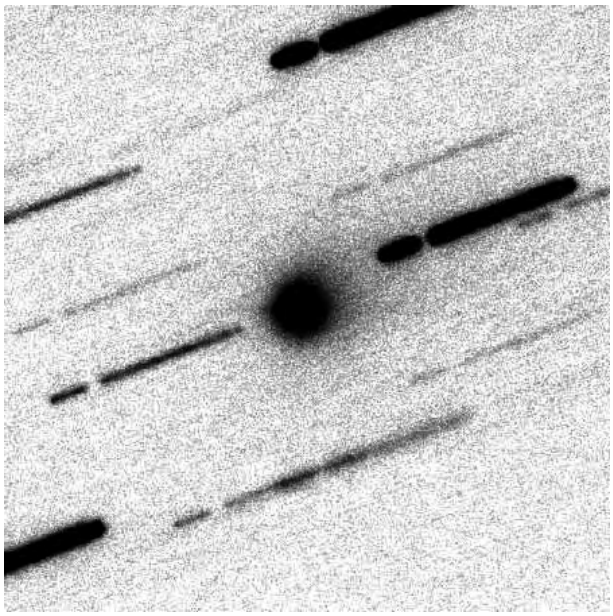

Figure 1. An *R*-band filter CCD image of Chiron obtained by Karen Meech and Graham Knopp with the University of Hawaii's 2.2 m telescope on 20 February 1993. Chiron was 9.31 AU from the Sun and 8.35 AU from the Earth, and had an apparent visual magnitude of 16.1 mag. North is towards the top and east is to the left of this 1.8×1.8 arcmin^2 image. Evidence of a coma can be seen as the haze surrounding Chiron; the dust extends about 15 arcsec (9×10^4 km) to the northwest. To correct for Chiron's motion against the background stars, this image is a composite made from 33 1 min exposures that subsequently were shifted to align with Chiron, and then added together to create an image with an effective exposure time of 33 min. Because of this 'shift-and-add' procedure, the stars appear as trails.

Observations: comet or minor planet?

As alluded to above, one of Chiron's unique features among the currently known Centaurs is that it has displayed a transient COMA, which has shown levels of activity that can be as high at aphelion as at perihelion. Indicative of its unusual nature, Chiron has two accepted designations, '(2060) Chiron' and '95P/Chiron', depending on whether one considers it as a minor planet or as a comet. However, Chiron is about 50 times larger than a typical comet.

Unusual activity was first detected by Dave Tholen, William Hartmann and Dale Cruikshank in 1988 when Chiron's brightness doubled while it was still at a distance of 12 AU from the Sun. Soon thereafter, a coma with a size of roughly 10^5 km around Chiron was observed by Karen Meech and Michael Belton. An image of Chiron and its coma is shown in figure 1. One explanation for this coma is that it comprises submicron dust particles that are escaping (entrained in volatile outgassing) from a low atmosphere. Marc Buie, James Elliot, Schelte Bus and more than a dozen collaborators observed Chiron during a stellar occultation in 1993, and their data show evidence of jet-like features, a common property in comets and inferred from models and other observations of Chiron. These jets imply that the coma is formed from a few active regions rather than a more pervasive sublimation over the surface.

The first ultraviolet spectrum of Chiron was obtained in 1995 by Noah Brosch with the long-wavelength spectrometer of the INTERNATIONAL ULTRAVIOLET EXPLORER satellite in low-resolution (6 Å) mode. One year later, the Faint Object Spectrograph on the HUBBLE SPACE TELESCOPE made ultraviolet observations at 2 Å resolution of Chiron during one of its outbursts. This 'outburst' consisted of a large (about 60%) increase in Chiron's flux, but curiously there was no evidence of an extended coma as one might expect in such a case. The source of this significant increase is unknown, and the analysis by Joel Parker, Alan Stern, Michel Festou and Michael A'Hearn suggests it may be tantalizing evidence of a highly unusual phase function, recoating of the surface from an unobserved outburst or a cold, persistent, near-surface 'fog' (small-scale-height atmosphere) that experienced a peculiar, unresolved outburst. Also, there is evidence that Chiron's color changed from gray to slightly blue during this outburst. The coincidence of this apparent color change with the flux increase may be the signature of small Rayleigh-scattering grains in Chiron's coma or on its surface associated with the higher albedo.

Chiron has exhibited activity at all points of its orbit, and there is a wide range in both the amplitude (from a few per cent to more than a factor of two) and the duration

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(from weeks to months) of these outbursts. In fact, Chiron was more active at its aphelion in 1970 than it was in following decades when it was closer to the Sun. Such an analysis (done by Schelte Bus, Edward Bowell, Alan Stern and Michael A'Hearn) of Chiron's activity was made possible by examining historical photographic plates from observatory archives.

The source of Chiron's activity is still an open question. Since Chiron is active at such large distances—e.g. beyond Saturn—its activity cannot be driven by sublimation of water-ice, which is not volatile at this distance (water-ice was first detected on Chiron by Michael Foster, Simon Green, Neil McBride and John Davies in 1998, and has been seen on other Centaurs by Robert Brown, Dale Cruikshank, and their collaborators). However, model calculations performed by Diana Prialnik, Noah Brosch and Drora Ianovici show that Chiron's observed activity pattern could be due to CO that is initially trapped in amorphous water-ice but then released when the ice is crystallized. Chiron's activity must be driven by ices that are volatile at these distances, and possible candidate species include CO, which is a common source of activity in comets, N_2, which is common on Pluto and Neptune's moon Triton, or CH_4. The variability of Chiron's outbursts, the apparent lack of a correlation between activity and distance from the Sun, and the observations of jet-like features imply that Chiron's surface may be unevenly covered with inert material.

Knowledge of the species driving Chiron's activity is the key to understanding its connection to other objects and regions of the solar system. In 1995, Maria Womack and Alan Stern made millimeter observations of Chiron when it was at a heliocentric distance of 8.5 AU. They detected carbon monoxide with a column density of $N(\mathrm{CO}) = 9 \times 10^{12}$ cm^{-2}, implying a production rate of $Q(\mathrm{CO}) = 2 \times 10^{28}$ s^{-1} if CO comes directly from the nucleus. This is comparable to the CO production rate of comet Hale–Bopp at heliocentric distances of 3.8 AU. The Hubble Space Telescope ultraviolet spectra provide the best upper limits to date for a number of other species. The data showed no evidence of coma emissions in CS λ2576, OH λ3085 or any other coma species, and they determined column abundance upper limits of $N(\mathrm{CS}) < 4.3 \times 10^{13}$ cm^{-2} and $N(\mathrm{OH}) < 1.5 \times 10^{14}$ cm^{-2}, corresponding to parent molecule production rates of $Q(\mathrm{H_2O}) < 4 \times 10^{30}$ s^{-1} and $Q(\mathrm{CS_2}) < 4 \times 10^{28}$ s^{-1}, respectively.

Chiron's future

It is still beyond the capability of modern instruments to make regular and detailed observations of the member objects of the Kuiper belt, so Chiron, due to its relative proximity, provides astronomers with the best opportunity to examine the properties of an object that was recently in the Kuiper Belt. Observations must continue to be made of its sporadic outbursts to discern the underlying mechanisms of its activity and the source of its coma. A significant step would be to make unambiguous detections and abundance measurements of the species comprising the coma gases. By the time Chiron returns for its next perihelion pass on 3 August 2046, our astronomical instrumentation and our understanding of Centaurs will hopefully have advanced to the point where we will be able to make detailed observations and analyses of its physical properties with respect to the Kuiper Belt. Perhaps we will even take advantage of Chiron's semi-centennial passage to launch a space mission to rendezvous with this unique emissary from the outer limits of our solar system.

Chladni, Ernst Florens Friedrich (1756–1827)

German physicist (acoustics). He collected meteorites. He claimed on the basis of a comprehensive catalog of accounts of finds and falls that he compiled that they fell from the sky. This view was comprehensively rubbished by the scientific establishment, especially the French Academy of Sciences, until convinced otherwise by BIOT's investigation of the fall of meteorites at L'Aigle.

Chondrites

The chondrites are the most common type of METEORITE falling to Earth from space. They acquire their name because most of them contain 'chondrules' (from the Greek, 'chondros', a grain) which are silicate beads sometimes found in large numbers. The chondrules have always fascinated scientists. The inventor of the petrographic microscope, H C Sorby, described them as droplets of fiery rain. They are essentially glassy beads made by a violent but brief heating event that caused dust grains to form millimeter-sized melt droplets. However, the cause of the heating remains a mystery. The most important feature of the chondrites is that, with the exception of a few highly volatile elements, they have the same composition as the Sun. They are also extremely ancient rocks, having formation ages comparable with the age of the solar system (4600 million years). Finally, they have unique textures suggestive of accumulation of diverse components with little or no subsequent alteration. In contrast, the ACHONDRITES are meteorites that have distinctly non-solar composition and are igneous rocks that formed by various types of volcanism.

The largest chondrite seen to fall from space is the 4000 kg Jilin, while the largest whose fall was not observed but for which the meteorite found on the surface of the Earth is the Tsarev chondrite that was found in Russia in 1968. The most famous chondrite is probably the ALLENDE METEORITE, which fell in Mexico in 1969. About 2 t were recovered strewn across farmland in Chihuahua province. The Allende chondrite is famous for the large number of white silicate aggregates with extraordinary chemical and isotopic properties. The 691 g Semarkona chondrite, which fell in India in 1940, is scientifically well known because it is the member of the largest chondrite class that most closely resembles original solar system matter.

Meteorites usually produce spectacular effects as they fall through the atmosphere, fireballs, many sonic booms and even smells are produced, and the surfaces of the surviving stones are blackened where a thin skin of material melted during atmospheric passage. The meteorites usually break into many pieces that are strewn over an ellipse on the Earth with the heaviest pieces travelling furthest. The Pultusk meteorite produced 100 000 fragments. About 850 chondrites have been seen to fall and placed in the world's museums, and nearly 20 000 fragments have been found on the Earth, mainly in North America, north Africa, central and western Australia and, especially, Antarctica.

This article describes the classification and basic properties of chondrites, their physical history as determined from isotopic studies, radiometric dating and petrology, and some current ideas for their origin.

Classification and basic properties of chondrites

The chondrite classes are indicated in table 1, along with information on their major properties. Also included are two classes of 'primitive achondrites'. These have traditionally been regarded as achondrites because of their igneous textures, but their composition is solar and it is now assumed that they are chondrites that melted without changing composition.

Although chondrites have the same proportions of most elements as the Sun, two volatile elements that are not present in solar proportions are sulfur and oxygen. The abundance of these elements, oxygen in particular, varies significantly among the chondrites. This has important implications for the minerals present. In the EL and EH chondrites (collectively termed 'enstatite chondrites'), iron is in the metal and sulfide form, but little or none is in the silicate form. The dominant silicate mineral is enstatite, $MgSiO_3$, after which the class is named. The H, L and LL chondrites (collectively termed 'ordinary chondrites') contain more oxygen than the enstatite chondrites. Thus while some of the iron exists as metal and sulfide, much is in the silicate form as the stony (silicate) minerals olivine and pyroxene. (Olivine is a solid state solution of Mg_2SiO_4 and Fe_2SiO_4, the Fa term in table 1 referring to the percentage of Fe_2SiO_4 present, while pyroxene is a solid solution of $MgSiO_3$ and $FeSiO_3$, the Fs term in table 1 referring to the percentage of $FeSiO_3$ present.) The CI, CM, CV and CO chondrites (collectively termed 'carbonaceous chondrites') contain more oxygen than the other chondrites and in some the iron no longer exists in the metal form but is entirely replaced with magnetite and similar minerals. The CARBONACEOUS CHONDRITES also contain higher amounts of volatile constituents than the other chondrites, the CI chondrites being 20% water and therefore best considered as rather hard balls of mud.

These properties can conveniently be displayed by a plot of iron in the metal form against iron in the sulfide and silicate form (figure 1(*a*)). On such a plot, first used by Nobel laureate Harold Urey and his colleague Harmon Craig, the chondrites will lie on a diagonal with oxygen-poor meteorites on the top left and oxygen-rich meteorites on the bottom. The diagonal will be the 'solar total iron' line if the ratio of iron to silicon is equal to the solar value. However, the chondrites move away from the solar diagonal, indicating that, in addition to the differences in the amount of oxygen they contain, some chondrites contain different amounts of total iron.

Other properties seem to vary with these chondrite classes, such as the abundance of highly refractory (non-volatile) elements that show small but significant decreases from solar as we go from carbonaceous to ordinary to enstatite chondrites. Similarly, the relative abundance of the three isotopes of oxygen in the different chondrite classes is highly characteristic. Carbonaceous chondrites (CI chondrites excepted) contain a greater proportion of the major oxygen isotope (^{16}O) than rocks from the Earth and Moon, whereas enstatite chondrites and CI chondrites have similar proportions to the Earth and Moon and ordinary chondrites have a lower proportion of ^{16}O. The biggest effects in oxygen isotopes are displayed by the CV chondrites and appear

to be related to the white silicate aggregates that are characteristic of this class.

The main questions posed by the chondrite classes is that, given that chondrites are ancient and that they are essentially solar in composition, how did these variations in iron chemistry, amount of iron and the other properties come about? What do they tell us about conditions in the early solar system?

One clue to the nature of the process that gives rise to these properties is the nature and abundance of the chondrules and the relative sizes of the chondrules and metal grains (figure 1(*b*)). The abundance of chondrules falls from about 75 vol% in the ordinary chondrites to 35 vol% in enstatite and CV and CO chondrites to less than 10 vol% in CM and essentially zero in CI chondrites. Chondrules are highly diverse, some containing iron-rich silicates and being relatively rich in volatile elements and some containing iron-poor silicates are being depleted in volatile elements. Thus it is at least arguable that some of the oxygen and refractory element trends in figure 1(*a*) reflect the abundance and proportion of the different types of chondrules. Metal grain size also varies considerably from class to class. Enstatite chondrites have the smallest and ordinary chondrites the largest metal grains, while carbonaceous chondrites generally have little or no metal.

History of chondrites

If one looks at a series from the same class under the microscope there is often a wide range of textures, with the chondrules being distinct in some chondrites and blurred in others. The chondrules are essentially grains of olivine and pyroxene surrounded by a material that is glassy in some chondrules, translucent in others and crystalline in yet others. Similarly, the matrix between the chondrules and metal grains is fine grained in some chondrites and coarse grained in others. In addition to these physical trends, the composition of mineral grains and phases becomes more uniform as textures become blurred. These effects are all attributed to heating of the rock after its assembly. The effect is known as metamorphism, and it is described by a numbering system from 3 to 6 with unmetamorphosed type 3 and heavily metamorphosed meteorites being type 6. From detailed studies of the chemistry of phases in chemical equilibrium we can estimate that types 3, 4, 5 and 6 correspond approximately to temperatures of 400–600 °C, 600–700 °C, 700–750 °C and 750–950 °C, respectively. Types 1 and 2 refer to chondrites metamorphosed in the presence of considerable amounts of water (∼50 vol%), the type 1 at 100–150 °C and type 2 at <20 °C. From compositional profiles in the metal of ordinary chondrites, caused by incomplete equilibration, we can estimate that cooling rates following metamorphism were typically 10–100 K Myr^{-1}.

Another process that most if not all the chondrites have suffered is reflected in the naked-eye appearance of the chondrites. They often appear to be made up of fragments of previously existing rocks. The Fayetteville meteorite (figure 2(*a*)) is an excellent example

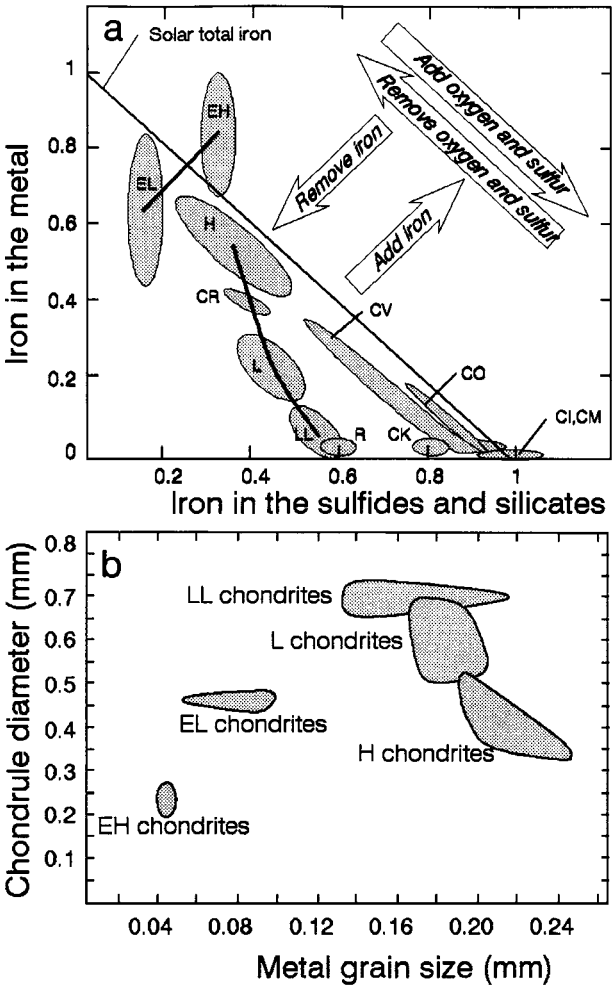

Figure 1. The basic properties of chondrites are summarized in these two plots. (*a*) Iron exists in three forms, as metal, sulfide and silicates. Plotting iron in the metal form (as ratio of iron atoms to silicon atoms) against iron the sulfides and metal produces several different fields, each representing a different chondrite class. How the classes relate in terms of adding or removing iron, sulfur and oxygen are indicated by the large arrows. (*b*) Physically, the chondrite classes are characterized by the size of their chondrules and metal grains. The carbonaceous chondrite classes are not shown because they contain little or no metal, but they do contain very large amounts of fine-grained silicate matrix.

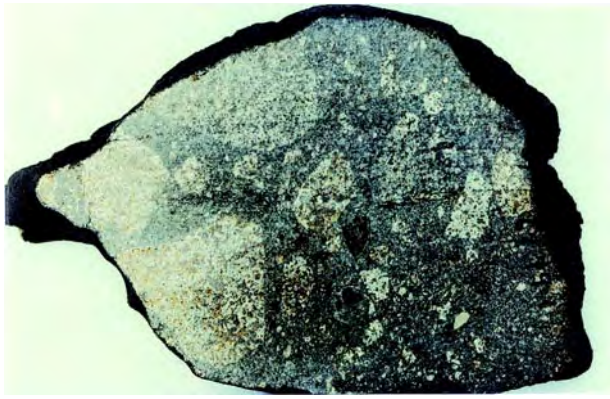
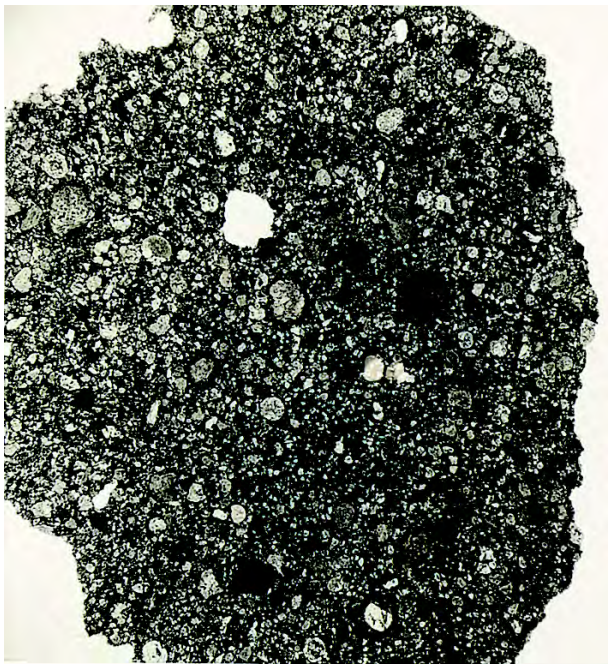


(*a*)



(*b*)

Figure 2. (*a*) A cut face of the chondrite that fell at Fayetteville, Arkansas, on 26 December 1934. The black fusion crust produced during atmospheric passage can be seen around the edge. The interior consists of light fragments of normal H chondrite embedded in a darker 'matrix' of crushed H chondrite material mixture that is physically similar to the 'soil' on the Moon. Fayetteville is a chondrite that is described as a gas-rich regolith breccia fron the surface of an airless body. The cut face is 9 cm in its longest dimension. (Johnson Space Center photograph S84-32404.) (*b*) A slice from the Indarch EH3 chondrite cut so thin that light can pass through and reveal its internal texture. The sulfide and metal grains are opaque and appear black, while the many chondrules appear as light gray circular objects typically 0.5 mm in diameter. The longest dimension of the thin section is 1.4 cm. (Smithsonian Institution photograph M-1249.)

of this texture. Technically, the process is referred to as 'brecciation' and the rocks are referred to as 'BRECCIAS'. Fragments of perfectly normal chondrite are sometimes surrounded by a darker 'soil' made of crushed chondrites and being rich in inert gases, carbon and crystals that have been damaged by radiation. These meteorites are referred to as 'gas-rich regolith breccias'. They were the surface debris of some airless body exposed to solar wind and energetic solar radiations. The Apollo astronauts found similar rocks on the Moon.

In addition to metamorphsim and brecciation, many meteorites show evidence for sudden excursions to high temperatures followed by very rapid cooling. Crystals are

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

cracked and deformed, and metal and sulfide minerals are melted and forced down cracks, and sometimes minerals acquire unusual textures. These effects can be reproduced in the laboratory by exposing the chondrites to shock waves produced by plastic explosives or large guns. The effects are classified as a series of levels, S1, S2, S3, S4, S5 and S6, that refer to shock pressures of <5 GPa, 5–10 GPa, 10–20 GPa, 20–30 GPa, 30–50 GPa and >50 GPa, respectively (1 Gpa, or gigapascal, is equal to about 10 000 atm). The source of the shock wave experienced by the chondrites is almost certainly impact between two ASTEROIDS in space.

Some of the best information we have on the history of chondrites is provided by various dating methods (figure 3). As soon as the meteorite is removed from its original parent body, and acquires meter-sized dimensions, COSMIC RAYS bombard the stone and create isotopes not otherwise present. From these isotopes it is possible to calculate the duration of exposure to cosmic rays. It is frequently found that large numbers of chondrites of a given class were exposed at the same time, and this is strong evidence that all or most of the chondrites were released from the same parent object at that time. The best example is the H chondrite class, most of whose members became exposed to cosmic rays 8 million years ago. Several other chondrite classes display similar peaks in their exposure age distributions.

A different dating method leads to the same conclusion for the other major chondrite class, the L chondrites. The 'Ar–Ar age' is based on the radioactive decay of ^{40}K to ^{40}Ar; the potassium is measured in the laboratory from the abundance of another experimentally produced isotope, ^{38}Ar. Most of the L chondrites have Ar–Ar ages of about 500 million years, and many of these are intensely shock heated. It thus seems that 500 million years ago all these separate L chondrites experienced a common heating event that caused a loss of the ^{40}Ar gas and a resetting of the Ar–Ar clock. They must also have been part of the same parent object at that time. The exposure and Ar–Ar ages are evidence that members of the large chondrite classes came from one or two objects in space.

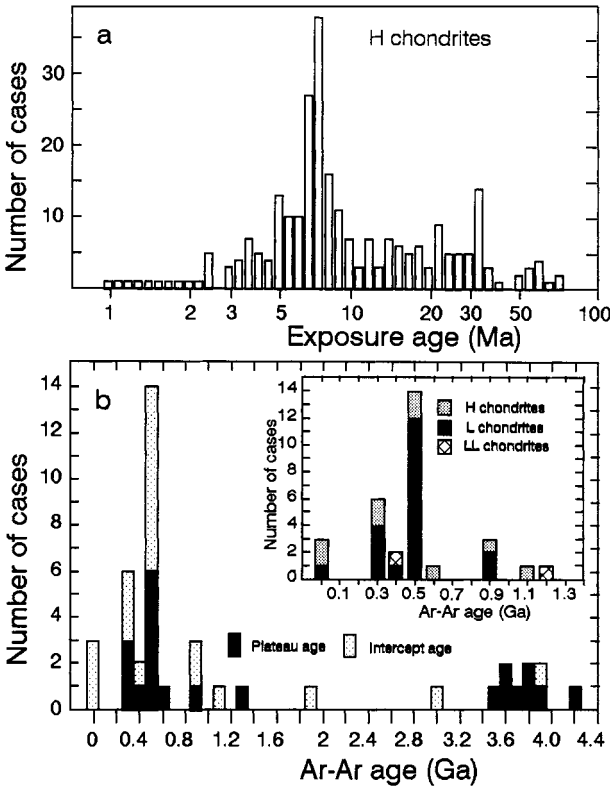

Figure 3. Two kinds of ages provide important insights into the history of the chondrite meteorites. (*a*) The duration of exposure to cosmic rays, calculated from the abundance of isotopes produced by cosmic ray bombardment of the meteorite. The peak in the histogram at 8 million years indicates that many or most of the individual meteorites falling to Earth were exposed to cosmic rays at the same moment and must have been part of the same single object prior to that break-up event. The data shown are for the H chondrites but other classes often show similar tendencies towards preferred cosmic ray exposure ages. (*b*) The Ar–Ar age essentially measures the time during which the ^{40}Ar accumulated in the meteorite as a result of radioactive decay of ^{40}K. The peak in the histogram at 500 million years shown mainly by the L chondrites indicates that at this time a large number of L chondrites had the Ar–Ar 'clock' reset to zero by loss of previously accumulated ^{40}Ar. Thus, most members of this class also experienced a common heating event at one time, indicating that they too were part of the same object at the time of that event. 'Plateau' and'intercept' ages refer to different ways to handle the data.

Origin of chondrites

So what were the objects from which the chondrites are coming? A handful of meteorites, mostly chondrites, were observed sufficiently well during fall that their orbits could be determined. The orbits resemble those of the NEAR-EARTH ASTEROIDS, coming within about 0.9 AU of the Sun and going out to the main ASTEROID BELT at about 2.5 AU (1 AU, the 'astronomical unit', is the distance of the Earth from the Sun, 150 million kilometers). The relationship between comets and asteroids is unclear, and as many as half the near-Earth asteroids could be extinct comet nuclei, but many could have come from the main asteroid belt.

The spectrum of the sunlight reflected from the surface of asteroids provides clues to their surface composition. Over 2000 asteroids have now been sorted into classes in this way, and many appear to resemble meteorites (table 2). However, asteroids with spectra resembling those of the ordinary chondrites, the chondrite class that dominates the Earth's meteorite flux, are very rare among the asteroids. Perfect matches are found for less that 1% of asteroids, and even if one assumes that some form of space weathering is affecting the asteroid surfaces, then less than 11% of the asteroids could be the source of the Earth's major chondrite classes. There are essentially two factors that determine which meteorites reach the Earth besides the abundance of their parent asteroids in the asteroid belt. These are the orbital

mechanism for transferring objects from the asteroid belt to Earth and the Earth's atmosphere. Passage through the Earth's atmosphere destroys most of the fragile CI and CM meteorites but leaves unscathed the tough ordinary chondrites. Nearly one-half of the classified asteroids in the main belt have spectra resembling those of CI or CM chondrites while only a few per cent of meteorites reaching the surface of the Earth are members of these classes.

Table 2. The asteroid classes, their relative abundance and meteorite matches.

Class	Abundance (%)	Meteorite match[a]
D	6.2	IDP
P	4.3	IDP
C	22.8	CI,CM
T	1.3	Sulfur-rich irons
B+G+F	9.1	CI,CM
Q	0.41	H,L,LL
V	0.41	HED
R	0.10	?
S (IV)	11.0	Lod, Win, OC, irons
S (others)	25.9	Pal, Ure, Bra, Lod, Mes, Win, Ste
A	0.71	Pal,
M	4.3	Irons, EC
E	1.3	Aub

[a] Meteorite classes most closely resembling the asteroid class. The chondrite classes are H, L, LL (ordinary chondrites, OC), CI, CM, CV, CR, CO, EH and EL (enstatite chondrites, EC); Win, winonites; EC, enstatite (EH and EL) chondrites; Bra, brachinites. Other classes: Ste, Steinbach; Mes, mesosiderites; HED, howardites–eucrites–diogenites; Aub, aubrites; Ure, ureilites; Pal, pallasites; Lod, lodranites; IDP, interplanetary dust particles.

We think that most of the ordinary chondrite classes are coming from single parent bodies, and spectral data show these objects to be rare in the asteroid belt. Recently it has been suggested that the H chondrites are coming from asteroid 6 Hebe, the '6' indicating that it was the sixth asteroid discovered. This 200 km object not only has a surface spectrum similar to that of H chondrites, mixed with some related IRON METEORITES, but also is located in space where both Saturn and Jupiter exert a strong periodic gravitational influence that could send meteorites from Hebe to Earth.

If we assume, as seems likely, that the various chondrite classes are coming from different asteroids, then how did the different classes originate? How did their parent asteroids have different surfaces? This is equivalent to asking how the chondrules in the meteorites formed and how the metal and silicate proportions came to differ from class to class. Most scientists argue that chondrite formation and metal–silicate separation occurred in the NEBULA, that lightning or other pulses of energy shot through the nebula dust to produce chondrules and that the metal and silicate grains swirling around in the nebula became separated, perhaps by aerodynamic sorting by the gas or perhaps by some other process. However, the present writer has suggested that both chondrule formation and metal–silicate separation occurred on the surfaces of asteroids. I have suggested that chondrules formed by impact and that metal and silicate grains became separated as gases from the interior of the asteroid, mainly water, passed through the dry surface layers, size- and gravity-sorting chondrules and metal, and adjusting their relative proportions, as they escaped to space.

So the origin of meteorites is essentially the same as the origin of asteroids. The nebula from which the Sun formed fragmented from the larger interstellar cloud and underwent gravitational collapse to produce the proto-Sun and a number of rings of material that quickly coalesced into planets. At the location of the asteroid belt, 2–3 AU from the Sun, the gravitational forces from the major planets (Jupiter and Saturn) were so strong that coalescence was prevented and a large number of tiny PLANETESIMALS formed. Some of these grew by ACCRETION but most fragmented by impact to form the asteroid belt much as we observe it today.

Many of the asteroids contained enough of the radioactive isotope of aluminum, ^{26}Al, that large amounts of heat were generated and they melted to produce the many igneous classes of meteorite. The daughter product of ^{26}Al decay, ^{26}Mg, has been found in aluminum-rich phases of certain meteorites. However, some chondrites were heated without melting, and many were not heated at all. Chondrites are very clearly primitive early solar system materials. Just to underscore this point grains of diamond, graphite, silicon carbide and aluminum oxide have been found in chondrites that have isotopic properties indicating that they were not produced in our own solar system but were ejected from the outer atmospheres of a variety of stars. They are presolar, INTERSTELLAR GRAINS. Thus, while chondrites are widely regarded as heralds bringing us information on the early solar system, in a very real sense they are a connection between our laboratories and processes occurring in interstellar space and distant stars

Christiansen, Wilbur Norman (1913–)

Australian radioastronomer, built a radioastronomy interferometer array, consisting of 32 antennas in an east–west line. It was built to investigate the Sun, and expanded with a north–south array (in what was called, after Christiansen, the *Chris-cross*) to produce true images. This radio-interferometer was used to make the first purely Earth rotation synthesis maps. The Fourier transforms, however, had to be done by hand, so a single contour map took half a year of hand computations to produce. Also carried out a preliminary 21 cm survey of interstellar hydrogen and detected two of the Milky Way's spiral arms.

Christie, Sir William Henry Mahoney (1845–1922)

British astronomer, worked at the Royal Observatory, Greenwich, as Chief Assistant (assistant director) before succeeding Airy as Astronomer Royal (director) in 1881. Turned the Royal Observatory towards astrophysics (as opposed to positional astronomy). He installed large collecting area telescopes (e.g. the 28 in refractor, still in operation, used originally for double star observations). He brought the status of the Prime Meridian of the world's international time zone system back for Greenwich from the Washington Conference of 1884. He expeditiously executed the work of measuring the positions of all the stars in the large Greenwich Zone (northern region) of the Astrographic Catalog. Founded and first edited *The Observatory* magazine, which still preserves a human face for British astronomy.

Chromatic Aberration

An optical defect whereby light rays of different wavelengths are focused at different points along the optical axis of a lens. Because the refractive index of glass is a function of wavelength, shorter-wavelength light is refracted (deflected) to a greater extent than longer-wavelength light. Consequently, shorter-wavelength light (for example, blue light) is brought to a focus closer to the lens than longer-wavelength light (for example, red). Since white light consists of a mixture of wavelengths, the image of a star, formed by a simple lens, consists, in effect, of a series of different-colored images spread out along the optical axis. The image formed at the blue focus, for example, consists of a blue dot surrounded by a halo of false color consisting of blurred images of varying sizes in the light of other wavelengths. Similarly, the image formed at the red focus consists of a red dot, surrounded by a blurred halo of colors. Between these two foci, there is a plane at which the smallest blurred image occurs, this image being called the circle of least confusion. Since this coincides approximately with the focus for light in the yellow-green part of the spectrum, to which the human eye is most sensitive, the best visual image is normally obtained when the eyepiece is adjusted to put this wavelength region into sharpest focus.

The spread of foci along the optical axis is called longitudinal chromatic aberration, and the spread in the plane containing the circle of least confusion is called transverse chromatic aberration. The degree to which the refractive index of an optical material, such as glass, varies with wavelength, is called the dispersion.

The effects of chromatic aberration can be considerably reduced by means of compound objective lenses that consist of two or more appropriately shaped components, each made of glass with different dispersions. An achromatic lens (or achromatic doublet), which has two components, can bring two wavelengths to the same focus and reduce the spread in focal lengths for the other wavelengths by about a factor of ten. A three-element apochromat reduces the spread even further.

Because the laws of reflection are independent of wavelength, chromatic aberration does not affect the mirrors that are used in reflecting telescopes.

See also: focal length, objective lens, refractor, spherical aberration.

Chromosphere

The chromosphere (Greek $\chi\rho\omega\mu\alpha$, color) is a gaseous shell atmosphere surrounding the Sun, and more generally stars, with a typical thickness of 2000 km, lying above the SOLAR PHOTOSPHERE and containing mainly hydrogen and helium gas.

Historical introduction

The total eclipse of 1860 may be regarded as marking the first serious study of the chromosphere. During eclipses the moon appears surrounded by a colored circle with some protruding structures, called PROMINENCES, which extend through the external corona and finer structures like 'poils' in French that would be the spicules. During the eclipse of 1970 C A Young used a spectrograph and a tangential slit. When the moment of totality arrived he was rewarded by the sudden appearance of numerous emission lines called a flash spectrum. This phenomenon lasted only a few seconds since the Moon rapidly covered the lowest layers of the chromosphere. In 1901 J Evershed published the spectrum of the chromosphere and discussed the similarities to and differences from the photospheric spectrum (table 1). During the latter part of the 19th century a new kind of instrument, *the spectroheliograph*, was developed at Mt Wilson by G E Hale and at Meudon by H Deslandres (see SPECTROHELIOGRAPH/SPECTROHELIOSCOPE). Observing in the H and K lines of ionized calcium (Ca II), they were successful and discovered the regular pattern of the chromosphere called the chromospheric network (see CHROMOSPHERE: NETWORK). The interpretation of these lines in emission above the limb was puzzling and nobody had in mind at that time that the chromospheric temperature could be higher than the photospheric one. We had to wait until 1942 for the discovery of the hot CORONA surrounding the Sun. A new instrumental development helped to give a better understanding into the chromosphere. In 1933 B Lyot published a report on birefringent filters with a narrow bandwidth which allowed the spicules at the limb to be seen. These filters became quite widely distributed and used in the 1950s and the fine structure of the chromosphere has been systematically studied, using the Hα line, as bushes of fine bright and dark structures tied in the network. These structures are called mottles. Outside of an eclipse the chromosphere can be observed with CORONAGRAPHS. This kind of instrument was first developed by B Lyot. The principle is based on the introduction of an artificial moon occulting the photospheric disk.

The principal characteristics of the chromosphere are its thickness of 2000 km and its basic temperature and pressure. Beyond the solar limb the chromospheric spectrum is characterized by emission lines. On the disk these lines appear as dark lines in the solar spectrum. They correspond to absorbed radiation at discrete wavelengths by elements of the chromosphere. The principal lines in the visible spectrum have been identified and are called the Fraunhofer lines (table 1). The intensity of the lines reflects the physical conditions of the plasma which absorbs or emits the radiation and is a good diagnostic of the plasma temperature. Above the photosphere, the temperature continues firstly to decrease to a minimum of 4200 K and then increases again.

Table 1. The strongest lines in the chromospheric spectrum (3200–9100 Å) classified by their intensity.

Wavelength (Å)	Element	Name of the line
6562.82	H I	Hα
4861.33	H I	Hβ
3933.66	Ca II	K
3968.47	Ca II	H
5975.65	He I	D_3
4340.47	H I	Hγ
8542.09	Ca II	
4101.74	H I	Hδ
8662.14	Ca II	
3999.65	H I	H_8
3970.07	H I	Hϵ

Morphology and dynamics of the quiet chromosphere

The aspect of the chromosphere depends strongly on the line used for the observations, and more precisely on the wavelength in which the image is obtained, e.g. Ca II H and K, Hα, He II 304 Å. The solar disk observed in Fraunhofer lines has a diameter slighter larger than the photospheric disk and is covered by a pattern very different from the granular pattern of the photosphere. In the H and K lines of Ca II the images of the chromosphere show a bright network surrounding more or less large cells which have a diameter of the order of 30 000 km (figure 1). This cell pattern overlies the photospheric supergranulation which is a manifestation of large-scale solar convection, an important mechanism for magnetic flux transport.

The H and K lines have a special profile with extremely broad absorption wings and a central emission. The central emission of the K line is called K3, the two adjacent maxima are called K2 (K2v violet wing and K2r red wing) and far in the wings it is called K1. Similar definitions are valid for the H line. The spectroheliograms in K1 show the photospheric pattern with granulation and sunspots. In K3 there is a mesh-like brightness pattern over the entire solar surface, which represents the network and the supergranules or the intranetwork, also called the internetwork. The network is more prominent in two symmetric zones north and south of the equator, located at tropical latitudes. In K2 very small bright points are visible over all the solar surface.

Network

The chromospheric network is directly related to the magnetic field. It appears brighter than the mean chromosphere owing to pressure and temperature variations and possibly heating in the magnetized atmosphere. The strength of the central part of the K line as measured in

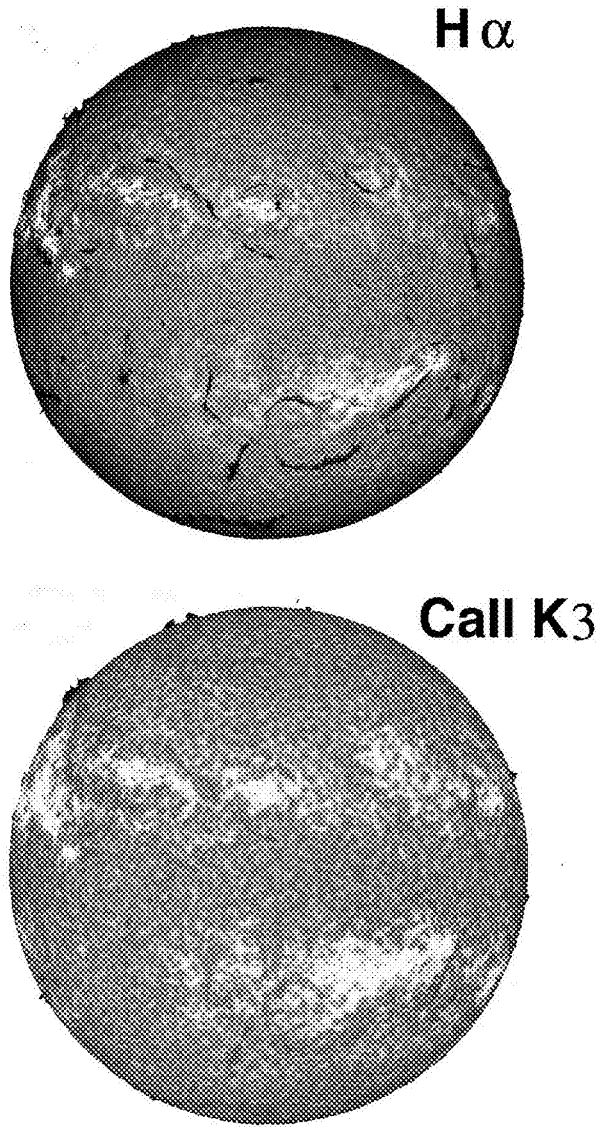

Figure 1. The chromosphere observed in the lines Hα of hydrogen and Ca K3 of ionized calcium in spectroheliograms obtained at Meudon (Courtesy of the Observatoire de Paris).

a 1 Å band is used as an index (K index) to define the local magnetic flux density in the underlying photosphere and is used for stars to define the degree of magnetism of the star. In the quiet Sun the K index increases linearly with the magnetic flux density.

However, this law is not true in magnetized regions (exceeding 400 G), where the power law decreases with an exponent lower than unity. This form is called the canopy effect (see CHROMOSPHERE: MAGNETIC CANOPY). The most conspicuous examples of canopy phenomena are associated with sunspots. The field forms a canopy over a non-magnetized region between 600 and 1000 km in the chromosphere (figure 2). The network is the site of the anchorage of coronal loops extending to coronal altitudes.

The Hα spectroheliogram (figure 1) has some similarities to the K3 spectroheliogram with two bright zones parallel to the equator. The network contrast is nevertheless weaker than in K3.

In the Lyman line (Lα) the network is much more enhanced than in Hα and is filamentary in appearance.

Bright grains

In K2 of the Ca II line, and better in UV lines, the network and the internetwork are grainier. The grains have a high contrast at wavelengths representative of the temperature minimum, e.g. in the continuum at $\lambda \sim 1600$ Å. The space imager of the TRACE satellite shows such grain patterns at high resolution. The continuum UV bright grains are observed everywhere as bright points. They have a characteristic size of 1000 km and a brightness temperature excess of 30–360 K.

In the network the bright points are generally associated with magnetic elements which collide. Most of the time they have opposite polarities and the bright points are due to heating of the plasma after reconnection. Magnetic flux is transformed to heat.

In the intranetwork, in high-resolution spectroheliograms obtained in the K2 or H2 wings of Ca II lines, bright grains (Ca II bright grain) are again well observed. For many years it was believed that they were due to the presence of small magnetic tubes like network bright points. The relationship of these bright grains to small magnetic elements has been subject to a long debate because the coalignment was not conclusive. It has been now proved that the bright grains are due to the behavior of chromospheric oscillations which produce shock waves (figure 2).

Fine structures

The Hα spectroheliograms (figure 1) show the chromospheric network but more distinctively the existence of very tiny small elongated structures. Gathered around sunspots are structures called fibrils (CHROMOSPHERE: FIBRILS). Thicker and longer structures in active regions or between active regions are called filaments. Tiny structures visible in emission above the limb are spicules. The small bushes of fine structures anchored in the network are mottles. These fine structures are controlled by the magnetic field which confines the plasma. The magnetic field plays an important role in the chromosphere (see below the definition of the plasma β).

Mottles

The mottles are irregular threads of large brightness contrast which link together to form quasi-regular pattern around and above supergranules in the photosphere. The mottles appear differently at different wavelengths in the Hα line. At the center of the line bright mottles are low lying (700–3000 km above the photosphere), while the dark mottles form a coarse fragmentation, but the admixture of bright and dark features makes the large-scale pattern less distinct than in the Ca II H and K lines in the quiet Sun.

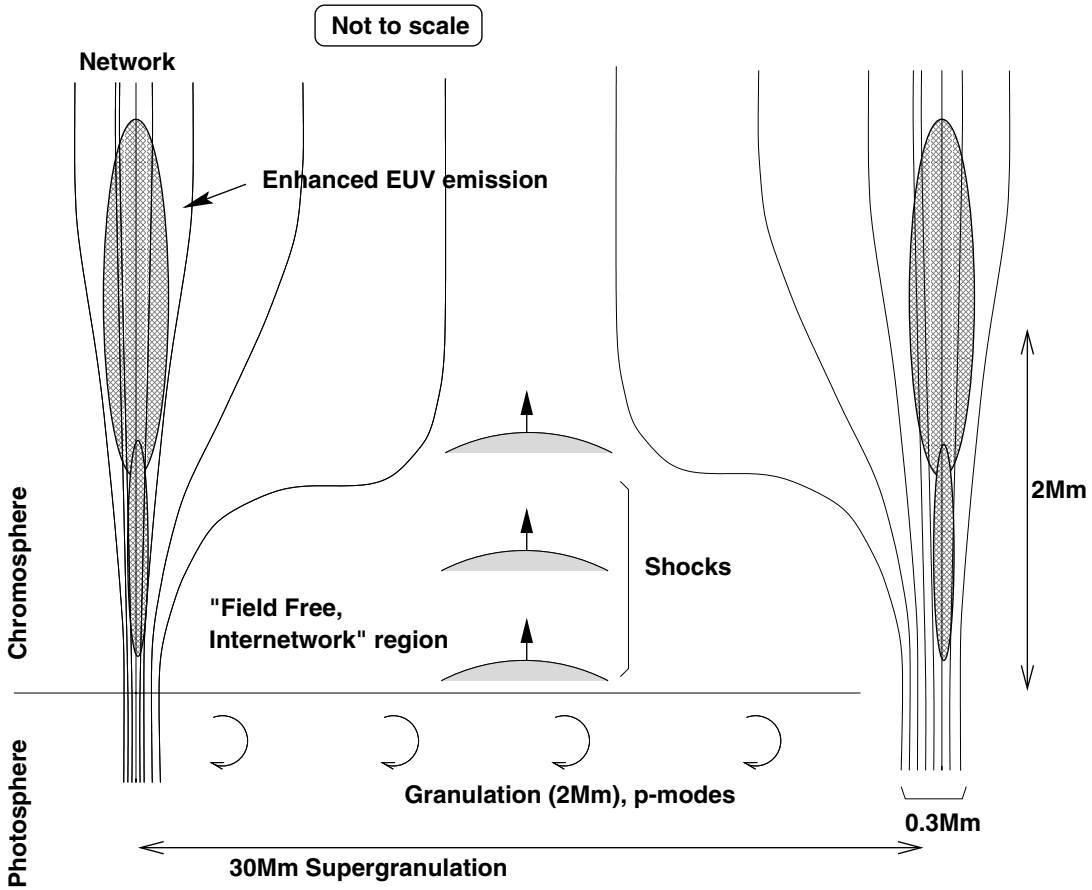

Figure 2. Diagram of the chromosphere (courtesy of P Judge).

Sometimes the fine structures take specific arrangements such as rosettes which have alternately bright and dark fine mottles radiating outward from a common bright center (figure 3). The bright core corresponds to a magnetic element of the network. The visibility of bright Hα mottles fades quickly as the observing wavelength is shifted from the center of the line. At 0.6 Å towards the blue wings of the K line only dark elongated mottles are found. Their intermittent clusters outline the supergranule cells. Seen near the limb at this wavelength position on either blue or red wings, the dark mottles retain their narrow shapes and often form in clusters or bushes.

In radio wavelengths (at 6 cm) the fine-scale network is resolved. All bright 6 cm features overlie bright Ca II K mottles.

The typical lifetime of mottles is 12–20 min. They are the sites of upward and downward motions with shorter lifetimes. A quasi-periodicity of 5–10 min is observed. Downward motions are well observed at the base of the mottles. They are evidently responsible for some bright grains owing to the compression of the plasma or an increase of the magnetic field strength. These downflows explained the common redshift observed in the network. The mottles can be regarded as cylinders of thickness $D = 500$–1000 km and of temperature $T = 8000$–$15\,000$ K. The pressure is about 0.5 dyn cm^{-2} and velocities are between 5 and 10 km s^{-1}. The difference between dark and bright mottles may be explained as due to an increase in gas pressure.

Spicules

At the limb, jet-like structures called spicules are observed extending to the hot corona (figure 4). Spicules have a temperature of 10 000 K and density of 10^{-13} g cm^{-3}. They rise to a maximum height of about 10 000 km with a velocity of about 20 km s^{-1}. Between 5000 and 30 000 spicules are present on the disk at any one time. The large number of spicules combined with their measured velocities implies an upward mass flux two orders of magnitude larger than that of the solar wind. This mass flux is large enough to fill the corona completely in 3 h. How does the mass flow come back to the chromosphere? It is tempting to try to find an answer in the downflow measured in the network and strongly visible at the basis of the mottles. Are mottles of the same nature as spicules? This has also been a subject of long debate and is still a matter of controversy. Nevertheless, spicules have been

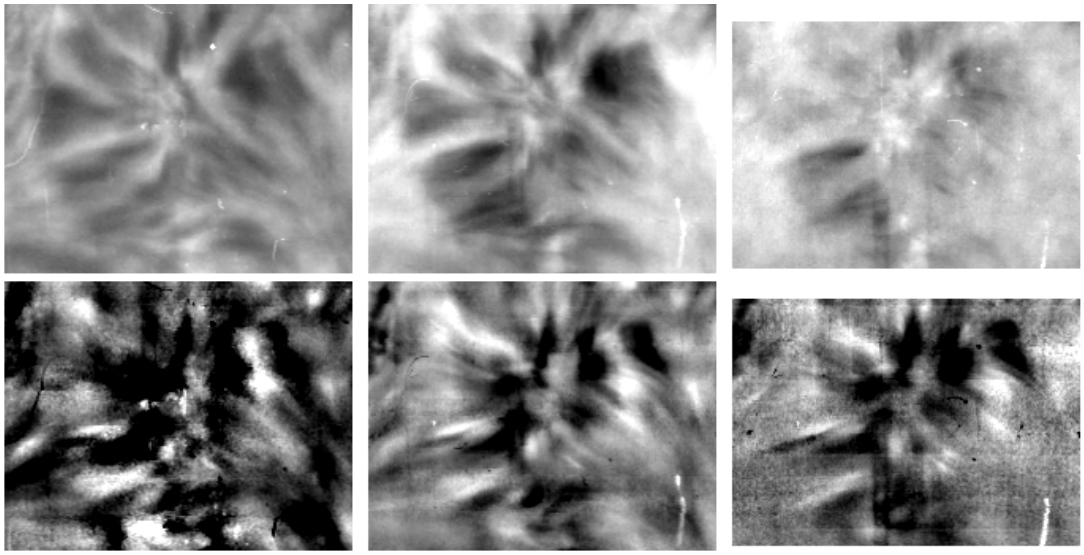

Figure 3. Observations of chromospheric mottles arranged as a rosette observed in the Hα line with the Multi-channel Subtractive Double Pass (MSDP) SPECTROGRAPH (Pic du Midi, Turret Dome). From left to right, the maps are obtained from near the line center to the far wings (H$\alpha \pm 0.25$ Å, ± 0.5 Å, ± 0.75 Å). The upper panels display intensity maps of a zone of dimensions 38 500 km $\times$30 000 km. The lower panels display Doppler-shift maps: dark regions represent downflows, bright regions upflows.

identified in filtergrams obtained for the disk in the far blue wing of the Hα line; which implies the existence of strong upward motions in these structures.

Physical conditions of the quiet chromosphere

The exploration of physical phenomena in the solar atmosphere by means of numerical simulations of atmospheric structure and spectral line formations is an essential complement to high-resolution observational study of the Sun. The principal goal of modeling efforts is to develop diagnostics of physical conditions and processes in the solar plasma. However, it is difficult to achieve this goal because of the variety of velocity fields, the thermal inhomogeneities, the small-scale geometry and the limit of computing resources.

It is universally agreed that the chromosphere is variable and inhomogeneous. Moderate spatial resolution observations in a wide variety of wavelength regions are combined into histograms which indicate the relative frequency of occurrence of different brightness levels. Semi-empirical model atmospheres have then been constructed to match the wavelength behavior of each brightness level. Fully three-dimensional model computational treatment of fine structures is too demanding to be practical, but simpler models in one dimension seem to give useful results. Such one-dimensional atmospheric models are derived for the quiet Sun, the sunspots and other structures. Using these models interpretation of the line profiles is possible and leads to knowledge of the physical parameters of the plasma where the line is formed.

Semiempirical models

To derive quantitative information about the physical parameters from the observed radiation, we have to understand the different processes concerning absorption of the incident radiation and emission by the atoms of the atmosphere. This parameter is called the source function of the plasma. We need to solve the equations of radiative transfer in an atmosphere where the assumption of local thermodynamic equilibrium (LTE) is not always satisfied. As a first step in the modeling the plasma is assumed to be static and the magnetic field is neglected. The non-LTE assumption involves detailed calculation of the statistical equilibrium of each atom (mainly hydrogen, the most important species) with as many atomic levels as necessary. For the basic model of the chromosphere a plane atmosphere is assumed as a simple geometry. A mean 1D semi-infinite atmospheric model is described by the variation in height of the temperature: the temperature minimum is 4300 K at around 500 km; it then rises to a plateau of 6000–10 000 K between 1000 and 2100 km. In the same height range (500–2100 km) the electron density decreases from 2.5×10^{11} to 2.5×10^{10} cm^{-3}, the gas pressure from 1.3×10^{3} to 1.5×10^{-1} dyn cm^{-2} and the density drops from 5×10^{-9} to 5×10^{-14} g cm^{-2}.

To fit the various types of radiation observed from different regions of the chromosphere different 1D models have been computed, e.g. models for intranetwork, network, SOLAR CHROMOSPHERIC PLAGE regions and flares. The brightness observed in Hα flares is explained by a rapid increase of the gas temperature in the chromosphere to nearly coronal temperatures. The brightness of plages is also due to higher temperatures, but for these structures

the magnetic field plays an important role and cannot be neglected.

Bifurcated models

Another view of the chromosphere is obtained from observations in the CO bands (band of carbon monoxide). These bands are optically thick at the base of the temperature inversion. The core of the strongest CO lines is not centrally reversed, contrary to predictions of the semiempirical models. Instead, the CO features exhibit a cool core which indicates the presence of a low temperature ($T < 4000$ K) above the temperature minimum height. Bifurcated models have been constructed to explain the formation of CO. It is admitted that a part of the chromosphere could be cold enough (see CHROMOSPHERE: THERMAL BIFURCATION).

Such a cool model ($T \sim 4000$ K until 1500 km height) has also been newly proposed in the simulation of intranetwork bright grains (chromospheric oscillations). The semiempirical models may not necessarily reflect an average chromosphere. This is an open question.

Formation of the lines

Semiempirical models nevertheless allow one to explain the central reversal of the H and K Ca II lines. The shape of the line profiles depends strongly on the profile of the temperature through the chromosphere and their regime of formation (by collisions or by radiation). If the line is controlled by collisions, as for example the K line of Ca II, the ratio between absorption and emission (the source function) increases in the chromosphere and the core of the line is self-reversed. If the line is controlled by radiation, as for example the Hα line, the source function is decreasing everywhere and the core of the line is in absorption without reversal.

UV lines are in emission because their source functions are higher than the chromospheric continuum intensity. For the Lyman lines the wings are formed in the chromosphere with the core in the transition zone at still higher temperatures.

At radio wavelengths (millimeter and centimeter), however, the radiation is nearly that of a black body at chromospheric temperatures.

Magnetized atmosphere and fine structures

While the photosphere is dominated by convection owing to its high gas pressure, the chromosphere is well structured by the magnetic field. The plasma is frozen in the magnetic field lines and so outlines the magnetic field structures. This property is useful to visualize the structures. Magnetic flux tubes, as they emerge because of magnetic buoyancy are pushed and concentrated into flux elements of a few hundred km in diameter, as a result of convective motions seen as granules and supergranules and of the so-called convective collapse. This concentration of flux leads to the formation of the chromospheric network, e.g. pores, faculae and sunspots. Photospheric motions and magnetic buoyancy may be the origin of the continued modifications of the coronal magnetic field and the dynamical events observed, i.e. on a small scale reconnection and on the large scale expansion. In the chromosphere the ratio between the gas pressure and the magnetic pressure β ($\beta = 8\pi p/B^2$) is already less than unity in most places, which implies that the magnetic pressure dominates. Flux tubes play an important role in the upward transport of energy and mass into the corona. The chromospheric velocity amplitudes are larger than the photospheric ones and can reach a mean value of 1–1.5 km s^{-1}. This confirms the validity of the continuity equation ($\rho VA =$ constant) in flux tubes with ρ the density, A the tube cross-section and V the velocity of the plasma.

Fine structures overlie the mean chromosphere. A discontinuity in the gradient of physical parameters of the atmosphere does exist and semi-infinite models are no longer valid; cloud-model techniques are more appropriate. In the classical case the structure is supposed to be a relatively thin cloud over a uniform atmosphere, and both of them contribute to the observed profiles. Since the first proposal of such a technique in 1964 by J Beckers, many investigations using such models have been carried out for mottles, waves and filaments.

Using the cloud-model method to analyse spectroscopic data, velocities as large as those of the spicules have been detected in mottles. Spicules should be mottles observed under certain physical conditions such as high speeds. The dynamics in the fine structures is various and large. Many models are proposed to explain the flows in such structures: they are based either on pressure-gradient pulses at the base of the structures or on siphon flows, or are a manifestation of wave motions in flux tubes.

Waves and heating

Oscillations in the chromosphere have been detected quite recently, with significant differences in both power and phase spectra between the intranetwork and network. Oscillations of around 3 min exist mainly in the intranetwork.

Three minute oscillations

The pattern of the intranetwork oscillations is well correlated with the pattern of p-mode oscillations in the photosphere. However, the slow network oscillations are not. They correspond to interferences with shock waves from the 5 min photospheric oscillations and 180 s period pervasive standing oscillations. The latter oscillations have an 80 Mm horizontal wavelength. They are not associated with magnetic flux tubes. The identification of the interiors of network cells with the basal chromosphere has revived interest in the origin of grains which are observed in Ca II H2v and K2v and intermittently present in C I. The 3 min oscillation could be associated with spatially unresolved 'clusters' of grains. Recent simulations of the generation of Ca II K2v bright grains by shocks of waves have been performed quite successfully by M Carlsson. The trigger mechanism of these waves is not yet fully understood.

Low-frequency oscillations

The network power is dominated by low-frequency oscillations with periods larger than 5 min (8–20 min). In bright network regions, at the boundaries of cells, random motions on scales of 2–10 arcsec have been detected. More recently, slow oscillations of 6–7 min have been identified by using the Lyman lines observed with the spectrometer SUMER aboard the space mission SOHO. These waves seem to propagate upwards and they are not spatially coherent. One possibility is that these oscillations are related to the pseudo-periodic behavior of mottles, or spicules, since they can produce such wave-trains. The bright features strong in the Hα far wing or in Ca II would correspond to the base of mottles and would be therefore of a magnetic nature.

Heating

Many oscillations are observed in the chromosphere. Are these waves heating the chromosphere? When acoustic waves travel upwards through the solar atmosphere, the density gradient results in an increase of the wave amplitude (V), so that the product ρV^2 remains roughly constant. Taking into account the observed velocities at low levels, it is possible to infer the height at which the amplitude reaches the sound velocity and thereby leads to a shock-wave formation. Shock waves can dissipate mechanical energy into heat by non-linear processes. Extensive calculations have been performed to explore the efficiency of such processes. It has been shown that heating by shock waves can be efficient in the low chromosphere, but at higher levels the acoustic waves should become evanescent and the available energy becomes too small to compensate for the radiative losses which are deduced from the observed spectrum. The recent discovery of bright grains has been explained in terms of the simulation of waves traveling in the chromosphere.

The active chromosphere

The active chromosphere involves all the manifestations of the solar activity observed in chromospheric lines (table 1). The solar activity is directly related to the magnetic activity and is manifested by the existence of active centers and newly emerging magnetic flux.

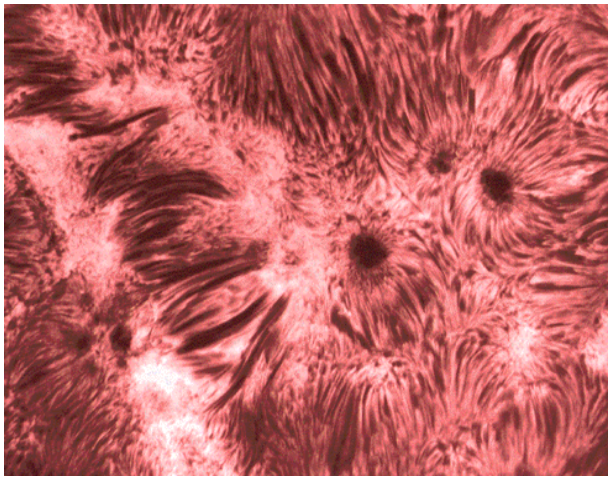

Figure 5. Chromospheric fibrils observed around sunspots and arch filament system in a active center (Pic du Midi, Turret Dome).

Active center

An image obtained in the Hα line at Pic du Midi (figure 5) shows the fibril pattern surrounding a sunspot. These structures are tied into the penumbra of the spot. They can be radially oriented or turning either clockwise or counterclockwise. It was recently discovered that the fibril pattern follows a clockwise orientation in the southern hemisphere and counterclockwise in the northern hemisphere. This helicity law seems to be important in the global view of the Sun's activity.

Some dark structures emerge with large velocities from the sunspot. They were discovered by Ellerman and are called Ellerman bombs (see SOLAR CHROMOSPHERE: ELLERMAN BOMBS). They are characterized by very broad emission profiles in the Hα line.

In an active center bright regions are observed, the so-called plages, or faculae. In old groups the sunspots disappear first and only faculae remain, which subsequently disperse and vanish.

Relation to the solar cycle

The normalized distribution of areas of active regions, using Ca II K plages or magnetic flux, varies with the phase of the solar cycle. The proportion attributed to plages and strong network in the total magnetic flux change varies by different amounts across the cycle, e.g. by a factor of 8 for plages, a factor of 40 for strong network regions and a factor of 10 for an activity complex.

The total enhanced network and plage signal is larger during active periods. The active network accounts for a large part of the total solar irradiance variation. This apparent solar cycle variation of enhanced intensity contrast is, nevertheless, only 2% for the network and 9% for plages.

Newly emerging magnetic flux

New magnetic flux emerges continuously and the full magnetic pattern of the Sun is renewed within 40 h. The emergence of flux has different consequences in the upper atmosphere and different signatures according the place where it appears. When new flux emerges at the center of supergranules it moves toward the edges and interact with the network magnetic flux. In the chromosphere the signature of an emerging dipole is an arch filament system. These arch-shaped tubes rise, reach an altitude of around 5000 km, bringing up denser material than in the surrounding atmosphere. At both ends of the arches the material falls owing to gravity with velocities of about 20 km s^{-1} which cannot be, nevertheless, considered as free-fall motions. In Hα the dense material appears as absorption features but in UV (SOHO) or in soft x-ray (YOHKOH the Japanese satellite) it appears in emission and brighter than the surrounding material.

Otherwise, the dynamic phenomena discussed above are related to solar activity. Twisting and shearing of flux tubes may set up currents along the field lines. On large scales differential rotation will induce an extended current system which increases continuously, leading to an outer expansion of magnetic field lines, which is visible with Yohkoh. The effective electrical conductivity of the solar corona is so high that the field structures resulting from flux emergence cannot immediately relax to a current-free state. The presence of currents can lead to the formation of different structures such as prominences, with any disruptions leading to eruptions such as SOLAR CORONAL MASS EJECTIONS or FLARES.

Chromosphere: Emerging Flux Regions

A description of the emergence of large concentrations of magnetic fields (active regions) at the solar surface is presented. The dark structures known as SUNSPOTS are a consequence of this process.

The emergence of an active region on the solar surface is one of the most prominent processes that can be followed by looking at the Sun on a daily basis. Regions that before emergence had the normal bubble convective appearance (GRANULATION) will in a few days develop dark sunspots and SUNSPOT PORES and bright FACULAE. At visible wavelengths (very often in the core and wings of the red Hα line) we can observe active region emergence in the deepest observable layers, the SOLAR PHOTOSPHERE and CHROMOSPHERE. Nowadays, we can also follow this process in the UV and x-ray spectral range from space, where we track active region emergence in the outermost layer of the Sun, the CORONA. It is in the chromosphere and in the corona where all the energetic processes relating to flux emergence can be followed more easily. The interaction of the newly emerging flux and preexisting field lines usually triggers a large number of FLARES (the sudden, transient release of energy probably related to magnetic reconnection). The dynamics observed in all these wavelength ranges clearly shows that active region emergence should be understood as the result of buoyancy rise of a magnetic structure from deeper layers in the Sun.

The magnetic field lines that form an active region are thought to be generated by some kind of DYNAMO mechanism (like almost all cosmic magnetic phenomena). The exact location of this dynamo within the Sun is not clearly established, but helioseismic studies suggest that the generation and storage of the dynamo fields take place close to the base of the convection zone (see SOLAR INTERIOR: CONVECTION ZONE). On the solar surface, the emergence of localized, vast amounts of magnetic fields suggest that, at the bottom of the convection zone, the field is organized into isolated magnetic flux tubes or ropes. These magnetic flux tubes are thought to be formed as toroidal loops in the interior of the Sun (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES). Their stability there remains controversial but it is clear that they develop a strong tendency to rise (at least, in part) towards the surface. This buoyancy comes from the extra pressure exerted by the magnetic field that reduces the gas pressure inside the loop (pressure equilibrium is a very efficient mechanism which can be assumed for these tubes). The lower gas pressure can be achieved only through lower temperatures and/or gas densities inside them. Thus, we are led to consider magnetic tubes, which, having lower densities, will develop some uncompensated buoyancy and rise (similar to bubbles in water, but with other physical agents playing an important role). The irruption of these magnetic bubbles into the solar atmosphere represents the emergence of an active region.

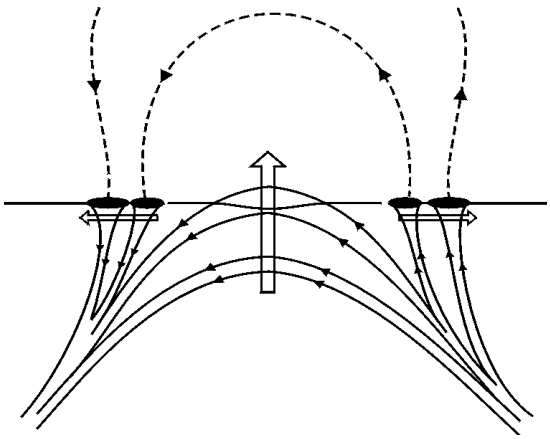

Figure 1. Illustration of the structure of an emerged Ω loop on the solar surface. The arrows indicate the proper motion of the field lines. The pores at the footpoints (black ellipses) separate from the central emerging region, where new horizontal flux is emerging. The dashed curves represent previously emerged field lines and already fill the coronal volume (from Zwaan 1992).

An active region usually has a clear dividing line between the two polarities (by polarities we mean here magnetic fields with their vectors pointing out of the Sun and fields pointing into the Sun). After emergence, the two polarities are seen at the surface separated in longitude. Magnetic field lines start at one polarity (figure 1, right), arch above the solar surface filling the solar corona (as seen from spacecraft such as Yohkoh and SOHO) and end at the other polarity (figure 1, left). In the deep (unobservable) layers, the field lines of both polarities dive down and connect with the system of toroidal flux tubes. This configuration of the field lines after emergence is called the Ω-shaped loop configuration by solar astronomers. An idealized sketch is shown in figure 1.

Observational description of emerging flux regions

The emergence of active regions in the solar atmosphere is a relatively easy phenomenon to spot in any of the spectral bands used to monitor the Sun. This is particularly true if we compare it with the more elusive reverse process of active region disappearance. Already in the late 1960s Bruzek (1967) presented a classical description of the emergence process as seen in the core of Hα (i.e. in the chromosphere). He coined the term arch filament system (AFS) to describe the system of parallel loops that connect the footpoints of an emerging flux region (EFR). These arching loops have since then been taken as the signature of the birth of an active region (see figure 2; a description of this EFR can be found in Strous (1994)). As seen in the chromosphere, the central portion of the AFS shows ascending velocities of up to 10 km s^{-1}, reflecting the upward buoyancy-driven motion of the magnetic system. Closer to the footpoints of the EFR, the loops show

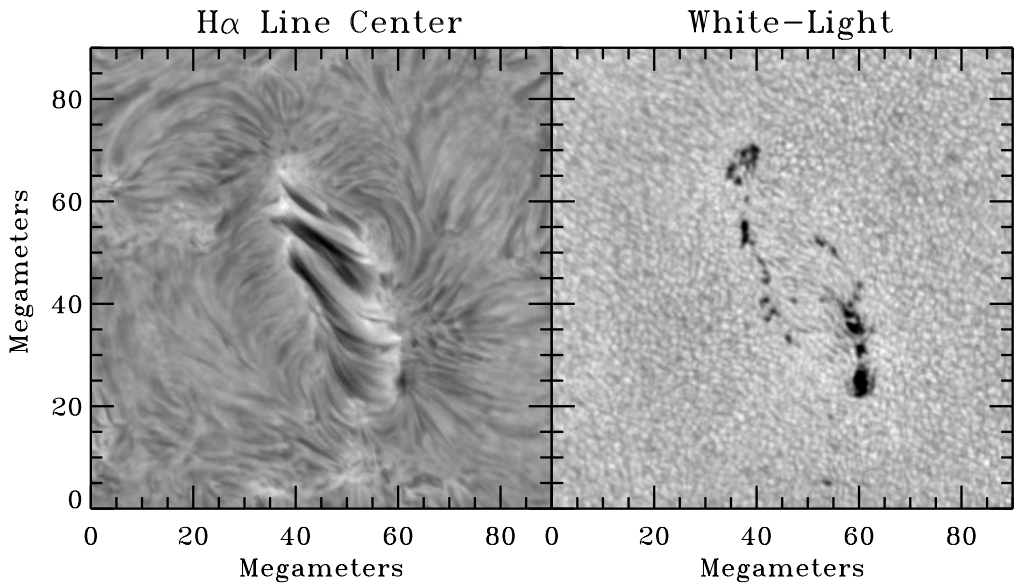

Figure 2. An EFR seen in the Hα line center (left) and white light (right) The footpoints of the EFR correspond to the two almost vertical alignments of pores. In between can be seen elongated intergranular lanes in the white-light image and the AFS in the Hα picture (the light and dark structures arching from one footpoint to the other). The images were taken at the Swedish Vacuum Solar Telescope on La Palma (Canary Islands, Spain). Image courtesy of L Strous/Swedish Vacuum Solar Telescope, Royal Swedish Academy of Sciences.

receding velocities of several tens of km s^{-1} produced by matter falling back along the magnetic field lines. During the process of emergence, the footpoints separate at a rate of a few km s^{-1} while new flux appears in between. The loops composing the AFS are in constant change (lifetimes of individual filaments $\approx$30 min) while they interact with new field lines rising from below. After a few hours, the flux system at the footpoints is organized into several pores, dark structures seen in white light where the normal granular appearance of the photosphere is absent. The magnetic field in these structures is able to impede the normal heat transport by convection (i.e. the granulation) and the reduced temperature of the gas makes them appear dark in contrast to the surrounding atmosphere. In the course of the days following the first sighting of the AFS, several bursts of magnetic flux emergence can occur and, quite often, it is in these later bursts where the bulk of the magnetic flux makes its way through the photosphere. The pores formed from all the different emergence episodes can eventually coalesce to give rise to a sunspot. This process is driven by the subsurface topology of the flux loop more than by any flow that may prevail there. This usually occurs in the leading (with respect to solar rotation) footpoint of the EFR and a stable round sunspot is observed. In the following footpoint, if a sunspot forms at all, it usually corresponds to a less stable (shorter-lived) structure with an irregular shape. This difference between the leading and following footpoints is very well documented but its origins are far from being fully understood. The AFS is seen while new flux emerges from below. This usually takes no more than 4–5 days.

Flux emergence as described above is consistent with the idea of an Ω-shaped magnetic loop that is rising through the solar convection zone (Zwaan 1992). During this rise, the loop passes through a highly stratified external atmosphere and interacts with convective motions. All this probably leads to the break up of the single initial loop into several loops (as depicted in figure 1). At the surface, each of them produces an emergence episode. The fact that different episodes can later give rise to pores that merge into a single sunspot indicates that deeper down the flux system has retained its identity.

Observations of EFR were first made in the chromosphere owing to the accessibility of the process as seen in Hα. Nowadays, the EFRs have also been followed in the photospheric layers, where we find dark alignments between the footpoints with elongated granules showing how the magnetic field perturbs the normal granulation seen elsewhere (see the white-light image in figure 2). Spectropolarimetric observations in photospheric lines have revealed downflows of up to 2 km s^{-1} close to the footpoints. These downflows are photospheric counterparts of the much stronger chromospheric downdrafts (due to the lower densities) mentioned above. In the photosphere, upflowing velocities of the central parts of the EFR have been detected that reach values of 1 km s^{-1}. It is clear that the field lines speed up as they rise through these layers to reach even higher upward velocities in the chromosphere.

Recent photospheric observations made with the Advanced Stokes Polarimeter (ASP; Lites *et al* 1998) have clarified several issues that had remained unanswered

before the use of high-sensitivity full Stokes polarimetry. This instrument allows reliable estimates of the mean vector magnetic field within the resolution element and the area fraction occupied by the field. These observations have clearly detected the horizontal (transverse) field lines as they pass through the photosphere, representing the signature of the top part of the emerging loops. The intrinsic field strength measured at the locations of the horizontal field lines is in the range 200–600 G, i.e. at or below equipartition with the kinetic energy of the granular motions. This result was expected from the fact that these fields are able to disturb the granulation pattern (Zwaan 1992). Fields in the range of 1200 G, or higher, are seen only in the vertical footpoints, in the form of either faculae or pores. It has been argued that the stronger fields found in the footpoints are achieved after the convective collapse process driven by the ubiquitous downflow found there. While this may well be the case, ASP observations have shown that the downflow is seen over regions that are already in the kilogauss regime; thus the downflow itself cannot be taken as the signature of convective collapse. The only way to ascertain whether this process is responsible for the high (twice equipartition) fields found in the vertical footpoints is by identifying a region of vertical weak field strength where a downflow develops and, after a short time interval (minutes), develops kilogauss strengths. This has not yet been observed and it represents an important challenge of modern spectropolarimeters in the present solar cycle.

Complex patterns of emergence

The Ω-shaped loop configuration of an active region described so far represents a simple bipolar system that describes most of the emergence cases observed on the Sun. This configuration fits in a natural way with Hale's polarity law. This law states that in a given solar hemisphere, during one solar cycle, the polarity of most of the active regions is oriented such that the positive polarity (field lines pointing out of the Sun) precedes the negative polarity (field lines pointing into the Sun). The reverse order would be found in the other hemisphere. The bipolar character of the Ω-shaped structures in each hemisphere will give rise to Hale's law. However, a small percentage of the emergence cases (around 1%) cannot be described by this bipolar configuration. Some active regions develop what is called a δ configuration, in which a single spot (the δ spot) contains within its penumbrae two umbral cores that have opposite polarities. The order of the two polarities is generally opposite to that predicted by Hale's law (in the above example the negative-polarity umbral core will precede the positive one). This δ-spot configuration, although rare, is very important because it represents the most flare-productive regions observed at the surface. δ groups are responsible for almost all great flares. The existence of complex neutral lines (where the polarity changes sign) seems to favor the occurrence of very energetic processes.

We have recently started to understand (Linton *et al* 1999) that this complex configuration may result from the evolution of toroidal loops as they pass through the solar convective zone. Some configurations of the magnetic field in these loops are liable to develop a twist of more than 90° in the top part of the Ω loop, thus inverting the polarity order. This kink instability develops during the rise of the loop. It will thus take place only if the timescale of the instability is shorter than the rise time. The inverted portion of the loop can turn into a compact sunspot displaying the two polarities at the surface. In some cases, the evolution can be complex enough (through field-line reconnection) to generate closed magnetic systems that ascend through the solar surface (Lites *et al* 1994).

Chromosphere: Fibrils

Fibrils are dark, elongated, curvilinear patterns in the CHROMOSPHERE as seen through a filter that isolates the Hα spectral absorption line of hydrogen. Well-developed fibrils occur in and around SOLAR ACTIVE REGIONS (figure 1) and SOLAR FILAMENT CHANNELS.

Like much of the traditional nomenclature used to describe the solar atmosphere, the term fibril is derived from Latin ('little fiber') and originates from the rich but limited view afforded by Hα images. Modern research on fibrils aims to relate their appearance to physical properties of structures in the atmosphere. An important component of this goal is to understand the relationship between fibrils and the fine structure of the quiet chromosphere. As seen in Hα, the quiet chromosphere is dominated by bright and dark mottles, structures which, although often elongated, are characteristically shorter in length, shorter-lived and show less large-scale organization than fibrils.

The prevailing hypothesis is that the magnetic field is the most important determinant of chromospheric fine structure. The difference in Hα appearance between quiet and active regions should therefore reflect differences in the organization of the field. There is considerable indirect evidence to support this hypothesis and none that contradicts it; but there are still few direct measurements of the magnetic field in the chromosphere.

Appearance

Traditionally fibrils are identified with dark features; but, as is apparent from figure 1, brighter and darker Hα features are closely associated. Even when the orientation of fibrils in a particular area is clear, it is often difficult to follow an individual dark feature for more than a few thousand kilometers. Large fibrils extend as far as 30 000 km; these are sometimes called chromospheric threads. The apparent width of fibrils ranges from 2000–3000 km down to the limit of resolution of ground-based images, about 300 km. Fibrils probably have structure or substructure on even finer scales, as the best images hint. The apparent aspect ratio (length to width) of fibrils ranges from about 3–4 (a less elongated feature would probably not be called a fibril) to as high as 30–40.

When an active region is born as an emerging flux region, the short fibrils that appear are called arch filaments (see CHROMOSPHERE: EMERGING FLUX REGIONS). The dark fibrils are intermixed with features that are distinctly brighter than the background chromosphere. Since emerging flux regions are always magnetically bipolar, and the opposite ends of an arch filament point to the opposite polarities, arch filaments support in a simple geometry the general hypothesis that fibrils follow magnetic lines of force. As the active region develops, the single arch filament system is replaced by a growing welter of fibrils that reflects the increasing size and magnetic complexity of the region. Sizable SUNSPOTS are surrounded by fibrils that begin in the white-light penumbra but often extend, in a superpenumbra, well beyond the penumbral boundary (see SUNSPOT PENUMBRA: STRUCTURE AND ACTIVITY). Superpenumbral fibrils in a complex active region are often strongly curved and non-radial. This is to be expected if fibrils follow the magnetic field. When the photospheric magnetic field is complex, even a potential field above the photosphere may be curved and non-radial around flux concentrations; when the photospheric field is highly non-potential, as it is often measured to be, strong curvature and 'S' shapes are expected. Thus, simple fibril patterns leading from one sunspot to another are the exception rather than the rule. Moreover, there are typically multiple episodes of flux emergence as the region grows. The fibril pattern fragments as magnetic field lines from newly emerged flux reconnect with existing flux.

A filament or filament channel may form within or on the boundary of the active region. Fibrils are indistinct within the channel; to either side, fibrils are aligned with the long axis of the channel. Measurements of the horizontal magnetic field within filaments indicate that the field runs predominantly along the axis of the filament, although the filament separates areas of opposite magnetic polarity at the photospheric level.

Long fibrils may form around the boundary of an active region, particularly in the directions of adjacent active regions, suggesting again that the fibrils follow magnetic connections.

A decaying active region is often dominated by a single large and regular sunspot. Close to the spot, its fibrils extend nearly radially outward. Distinct superpenumbral fibrils may extend twice as far as the penumbral boundary and occasionally exhibit a vortical pattern due to interaction with the solar rotation.

A large fibril often appears to obscure brighter structures, suggesting that the fibril is higher in the solar atmosphere. In this respect fibrils are analogous to dark mottles in quiet regions. It is difficult to give a range of heights for fibrils. Height is difficult to measure in individual cases, varies along a fibril, and varies between superpenumbral fibrils, short fibrils in magnetically complex areas, and long fibrils that could as well be called active-region loops. The appearance of fibril systems seen in perspective near the limb suggests that fibrils are elevated by 3000 km or more above the background chromosphere. Arch filament systems are seen to extend to heights of 10 000–15 000 km.

Dynamics

An arch filament system lasts for 1–3 days. An individual arch filament has a shorter lifetime, about 10–30 min. The top of an arch filament system rises with an apparent velocity $v \lesssim 20$ km s^{-1}, consistent with its identification with emerging magnetic flux. Material appears to flow downward along the arches with $v \approx 30$–50 km s^{-1}.

The general fibril pattern of a well-developed region evolves gradually, over a period of hours, and can remain recognizable for days. In this respect fibrils are more stable than dark mottles in quiet regions. The natural

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

interpretation is that the overall magnetic structure of an active region is determined by large and relatively long-lived concentrations of magnetic flux, whereas dark mottles surround small flux concentrations, usually associated with the CHROMOSPHERE NETWORK, that change on timescales of minutes to hours. However, individual fibrils have a shorter lifetime than their geometrical pattern, ranging from about 1 min for the smallest fibrils to 20 min for the largest.

The superpenumbral fibril pattern of an isolated sunspot changes even more slowly than the fibril pattern of a mature active region. The lifetime of an individual superpenumbral fibril is about 3–40 min, somewhat longer than the lifetime of a fibril in a younger active region but still much shorter than the lifetime of the pattern. The most characteristic dynamic feature of superpenumbral fibrils is a material flow along their length, inward and downward, of 5–20 km s^{-1}.

This inverse Evershed effect in the chromosphere contrasts with a slower outward flow in the penumbra at the level of the photosphere (see SUNSPOTS: EVERSHED EFFECT). Chromospheric outflow also occurs in a minority of superpenumbral fibrils.

It is difficult, using ground-based observations disturbed by atmospheric turbulence, to decide whether there is a one-to-one correspondence between the flow field and Hα brightness. Some high-quality observations suggest that flow channels usually coincide with fibrils, but not precisely or always. Like fibrils, individual flows often change beyond recognition in a matter of minutes, whereas a flow pattern can persist for hours. Active-region chromospheric flows not associated with sunspots have been studied less thoroughly than penumbral and superpenumbral flows.

Interpretation

Why are fibrils dark? How high are they in the solar atmosphere? How hot and how dense are they? What is the direction and strength of the magnetic field within them? How do these physical quantities compare with their values outside a fibril at the same height?

Fibrils have been recognized and studied for many years, yet the answers to these questions are surprisingly tentative for two main reasons: because fibrils are defined by their appearance in Hα, and it is easier to acquire high-quality images in this absorption line than it is to interpret them; and because it is difficult to measure magnetic fields in the chromosphere.

The quantitative interpretation of Hα images can be framed in terms of a contrast profile, $C(\lambda) = (I - I_0)/I_0$, where $I(\lambda)$ is the Hα intensity profile in the fibril and $I_0(\lambda)$ is a reference profile representing the inter-fibril chromosphere. Although the contrast profile is not a necessary construct in the task of reproducing $I(\lambda)$, it is conceptually useful for two reasons. First, it captures a defining characteristic of a fibril: that it be dark *relative* to its surroundings in the core of Hα. Second, if fibrils are indeed higher in the atmosphere than inter-fibril regions, it may be possible to approximate the fibril as a cloud-like feature that is illuminated from below by a background radiation field that is close to that of the average chromosphere. Most analyses of Hα contrast profiles employ (or critique) some variant of the cloud model described below.

Several observational considerations apply to contrast profiles. First, the wavelength resolution should be a small fraction of the width of the Hα line, which is about 1.5 Å (full width at half depth). Spectrographs and the best narrowband filters routinely achieve 100–125 mÅ (full width at half maximum transmission), but many Hα images are acquired with filters that have a bandpass of 0.25–0.5 Å. A theoretical contrast profile must be convolved with the filter bandpass before comparison with such images. Second, filtergrams should be acquired at more than one wavelength; otherwise it will not be possible to separate changes in the shape of the line profile from wavelength shifts due to the Doppler effect. The images at different wavelengths should not be separated in time by more than a minute or so, lest the fibril undergo significant evolution during the sequence. Third, the comparison between theoretical and observed contrast profiles should, ideally, take the effects of atmospheric seeing and instrumental stray light into account—but this is difficult. Finally, the concept of a background profile is only a first approximation. The inter-fibril atmosphere is not necessarily like the 'quiet' photosphere, nor constant from place to place.

The basic cloud model (attributed to J Beckers) follows the transfer of spectral line radiation through a discrete feature:

$$I = I_0\,\mathrm{e}^{-\tau} + \int_0^{\tau} S\,\mathrm{e}^{-t}\,\mathrm{d}t$$

where $I_0(\lambda)$ and $I(\lambda)$ are the intensities entering and leaving the feature, $S(\lambda)$ is the line source function, and $\tau(\lambda)$ is optical depth. Detailed nonlocal thermodynamic equilibrium (NLTE) analysis of the formation of the solar Hα line has established that, within 2–3 Doppler widths of line center: (a) the absorption coefficient has a Gaussian (Doppler) profile; and (b) the source function is nearly independent of wavelength, reflecting the dominance of non-coherent scattering. The first result, together with an assumption that the Doppler width of the absorption coefficient is constant along the line of sight, means that the optical depth will also have a Gaussian form

$$\tau(\lambda) = \tau_0 \exp[-(\lambda - \Delta\lambda_v)^2/\Delta\lambda_D^2]$$

where λ is measured from the center of the reference profile I_0, $\Delta\lambda_D$ is the Doppler width, and $\Delta\lambda_v$ is the line-of-sight velocity of the feature with respect to the reference. The second result, together with an assumption that the source function is constant along the line of sight through the cloud, allows the transfer equation to be integrated to yield

$$C(\lambda) = \left(\frac{S}{I_0(\lambda)} - 1\right)(1 - \mathrm{e}^{-\tau(\lambda)}). \qquad (1)$$

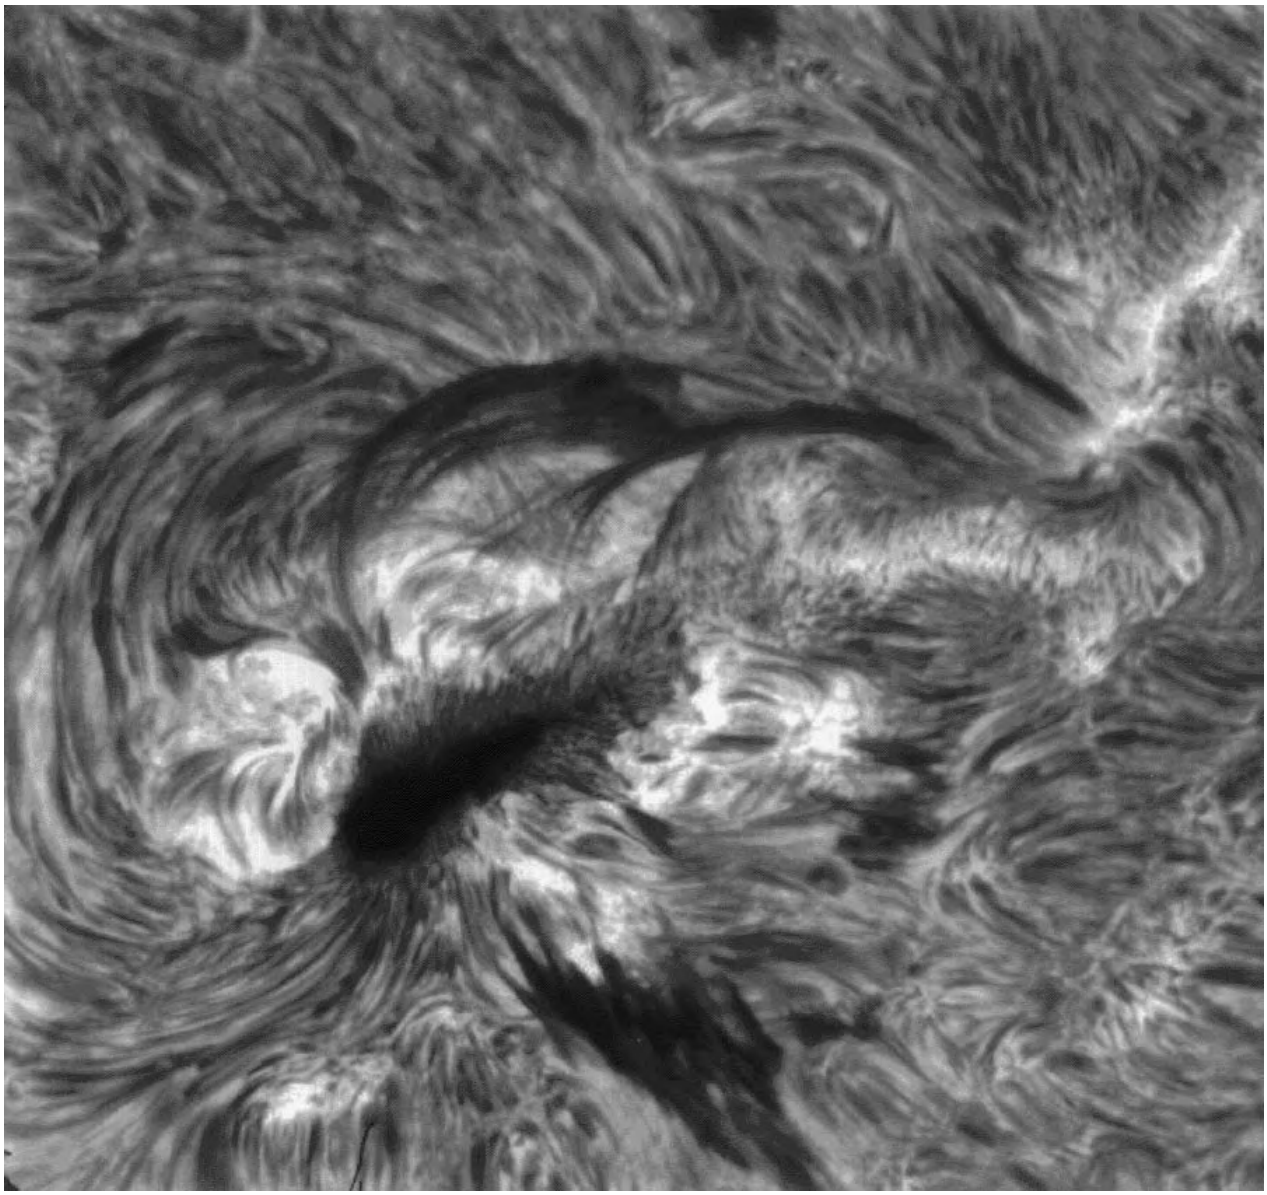

Figure 1. Chromospheric fibrils in a solar active region. Seen through a filter that isolates the core of the Hα absorption line, fibrils appear as thin, elongated dark features up to 30 000 km long, intermixed with brighter features (the area shown is about 200 000 km on a side). The largest and darkest features, above and below the sunspot, are called active prominences or filaments rather than fibrils. Image from Big Bear Solar Observatory.

The model is applied by adjusting the parameters S, τ_0, $\Delta\lambda_D$ and $\Delta\lambda_v$ through nonlinear least-squares fitting to achieve best agreement between equation (1) and the observed contrast profile.

A number of questions naturally arise concerning the applicability of the cloud model. Can it produce contrast profiles that agree with observations? Is it physically consistent? Is it realistic? What is learned from the fitted parameters?

Figure 2 illustrates the variety of contrast profiles that the cloud model yields for various reasonable combinations of the parameters. The contrast depends on wavelength in the line and can be negative (dark) or positive (bright). The profile is asymmetric if the cloud has a non-zero line-of-sight velocity.

The cloud model has been more extensively applied to structures in the quiet Sun (bright and dark mottles) than to fibrils and loops in active regions. The majority of observed contrast profiles of mottles can be adequately fitted by the model. Figure 3 gives an example of the model fitted to observations of an active-region loop.

The form of equation (1) does place two simple

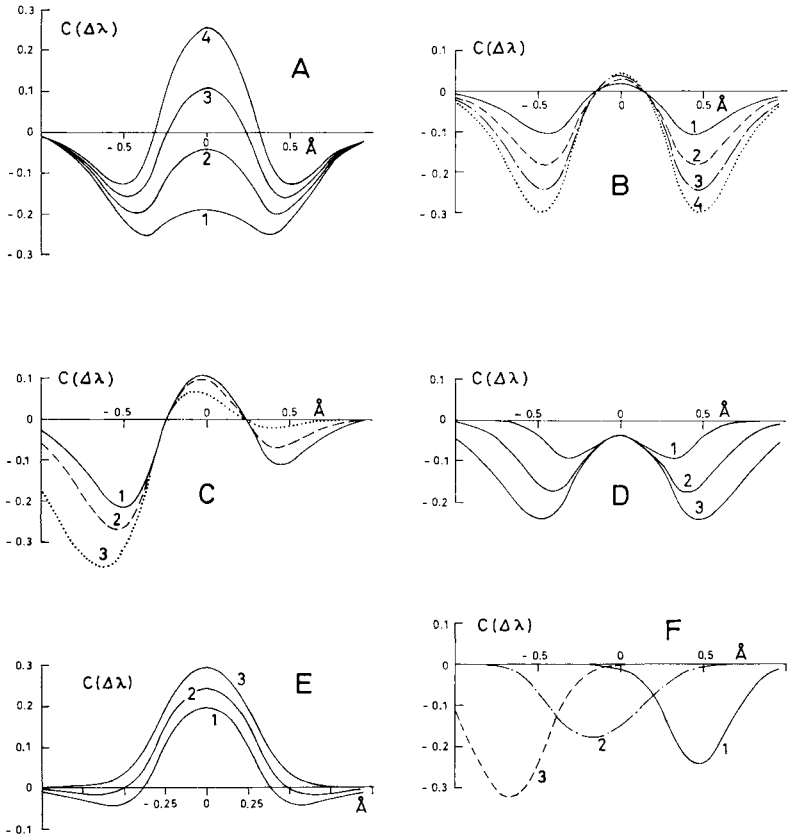

Figure 2. Theoretical contrast profiles from the cloud model. Each panel shows the effect of varying one parameter while holding the others constant. A: varying S/I_0. B: varying τ_0. C: varying $\Delta\lambda_v$. D: varying $\Delta\lambda_D$. From Grossman-Doerth U and von Uexküll M 1971 *Solar Phys.* **20** 31–46.

restrictions on the theoretical contrast profile. First, if $S < I_0(0)$, then $S < I_0(\lambda)$ for all λ, because the reference profile has its minimum intensity at $\lambda = 0$. Thus, if a feature is dark at unshifted line center, then it must be dark everywhere in the line. For fibrils, this seems to be true within the observational uncertainties. Second, since

$$\frac{C(+\lambda)}{C(-\lambda)} = \frac{1 - e^{-\tau(+\lambda)}}{1 - e^{-\tau(-\lambda)}}$$

and the right-hand side is always positive, the contrast at equal wavelength displacements from unshifted line center must have the same sign. This condition is automatically satisfied for features that are dark at all wavelengths; it is sometimes observed to be violated for other types of features.

In short, a cloud model can be reasonably fitted to most dark features in Hα. However, this does not ensure that the model is physically meaningful. A basic objection is that, for any particular geometry of the absorbing structure with respect to the underlying atmosphere, the source function is determined by the optical depth, Doppler absorption width and bulk velocity of the gas in the structure. Thus, it is not physically consistent to fit the parameters of the cloud model independently. When the cloud model is compared with treatments in which the source function is derived from NLTE theory, it is found that the results agree fairly well for 'high' clouds—those that subtend an angle much less than one radian as seen from the base of the background chromosphere. For 'low' clouds, the cloud model is unreliable: it may not fit at all, and even when it does, the values of the fitted parameters need not correspond to their physical values. A low cloud violates a basic assumption of the model, that the clouds have no back-reaction on the underlying chromosphere.

Other assumptions of the cloud model (constancy of the source function, Doppler width and bulk velocity along each line of sight, and global invariance of the reference line profile) are not as fundamental and can be relaxed in the form of multi-cloud or differential cloud models.

Whatever model is fitted to the observations, the goal is to estimate the values of physically interesting parameters. From Hα observations, the gas density and pressure can be estimated fairly well, but the kinetic temperature is poorly constrained.

The profile-integrated absorption coefficient in the Hα

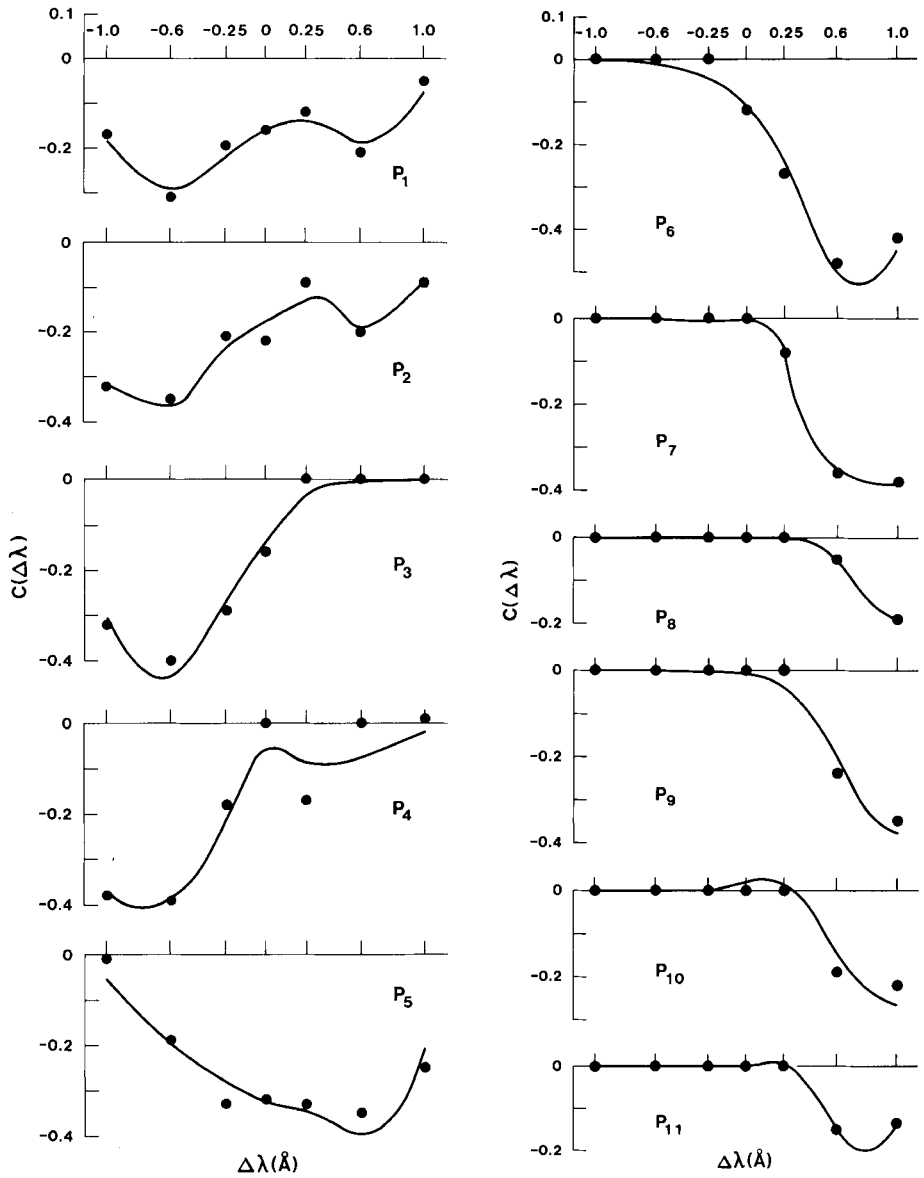

Figure 3. Observed contrast profiles (points) and fitted cloud models (curves) for an active-region loop. (From Bray R and Loughhead R 1983 *Solar Phys.* **85** 131–140.)

line (neglecting stimulated emission) is given by

$$\kappa_\lambda = \frac{\pi e^2}{mc}\frac{\lambda^2}{c} f_{\rm abs} N_2$$

where e and m are the charge and mass of the electron, $f_{\rm abs}$ is the absorption oscillator strength, and N_2 is the density of absorbers (here, the second level of hydrogen). If this absorption is distributed over a Doppler profile, the absorption coefficient at the center of the profile is

$$\kappa_0 = \frac{\pi^{1/2} e^2}{mc^2}\frac{\lambda^2}{\Delta\lambda_D} f_{\rm abs} N_2.$$

Within the cloud approximation, $\tau_0 = \kappa_0 L$, where L is the thickness of the structure along the line of sight, and, inserting numerical values

$$N_2 = 7.3 \times 10^7 \tau_0 \Delta\lambda_D / L \ {\rm cm}^{-3}. \qquad (2)$$

A cloud model gives τ_0 and $\Delta\lambda_D$. The thickness L is estimated from the observed transverse dimension of the fibril (atmospheric seeing and substructure along the line of sight can both contribute to an estimate higher than the true value). Equation (2) than leads to a typical range $N_2 = (1\text{–}5) \times 10^4$ cm^{-3} for a variety of dark features including fibrils. NLTE models of gas slabs irradiated

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

by photospheric and chromospheric radiation consistently yield an approximate relationship between N_2 and N_e, the electron density: $N_e = 3.2 \times 10^8 N_2^{1/2}$. Applying this relationship to the range just given for N_2 yields a range $N_e = (3\text{–}7) \times 10^{10}$ cm^{-3}. The total number density of hydrogen (neutral plus ionized), N_H, can be derived if the ionization fraction $x \equiv N_e/N_H$ is known. NLTE models yield values of x as small as 0.4 for thin ($L \approx$ 500 km), cool ($T \approx 7000$ K) slabs to essentially complete ionization for temperatures much above 10^4 K, leading to a derived range $N_H = (0.3\text{–}2) \times 10^{11}$ cm^{-3}. As the ambient density at heights greater than a few thousand kilometers is $N_H \approx 10^9$ cm^{-3}, fibrils are typically much denser than their surroundings. The derived gas pressure, $p_g = N_e kT(1 + 1.085/x)$, has a smaller range because of the opposing effects of temperature and ionization, $p_g = 0.1\text{–}0.3$ dyn cm^{-2}. All these ranges should be treated cautiously, as encompassing the majority, but certainly not all, structures that could be called fibrils.

It is not surprising that the temperature within fibrils is poorly constrained by Hα observations because the source function is dominated by photoionization due to the external radiation field rather than by internal collisions. NLTE slab models set an upper limit of about 2×10^4 K; at higher temperatures, the contrast is positive at line center for all reasonable values of the other parameters. The typical range $\Delta\lambda_D = 0.4\text{–}0.6$ Å yields a consistent but also weak constraint from the relationship $\Delta\lambda_D = (\lambda/c)(\xi^2 + 2kT/m)^{1/2}$: $T = (7\text{–}40) \times 10^3$ K for a microturbulent velocity in the range $\xi = 10\text{–}20$ km s^{-1}. As the ambient temperature at heights greater than a few thousand kilometers is $T \approx 10^6$ K, fibrils are typically much cooler than their surroundings.

The strength of the magnetic field within fibrils is not known with any confidence from direct measurement. Limited measurements of the direction of the field using chromospheric lines are consistent with the hypothesis that fibrils follow magnetic lines of force. This is also consistent with the fact that a field of 10 G corresponds to a magnetic pressure $p_{mag} = B^2/8\pi = 4$ dyn cm^{-2}, an order of magnitude greater than the gas pressures estimated above. The field is expected to exceed 10 G throughout the high chromosphere and low corona of an active region and may often exceed 100 G, so $\beta \equiv p_{gas}/p_{mag} \ll 1$ should apply within a fibril. The dynamic pressure $\rho v^2/2$ of gas flowing at 30 km s^{-1} is comparable to p_{mag} for $B = 10$ G.

The line-of-sight velocity of the material at some point along a fibril is sometimes estimated either from the Doppler shift of the line (the wavelength displacement of the bisector of a chord at a chosen depth in the line profile) or by noting the wavelength at which that material appears darkest (has the highest absolute value of contrast). Velocities estimated by the naïve contrast method are almost uncorrelated with velocities inferred from the cloud model and should not be used. Velocities estimated from the Doppler shift typically agree in sign with cloud velocities but are several times smaller in absolute value. Velocities derived from the cloud model should be more accurate than either of the simpler methods. Velocities so derived for arch filament systems and large fibrils are often supersonic at some points along the structure for any allowable value of the gas temperature.

Future research

Although fibrils are defined by their appearance in Hα, the analysis of Hα spectra reveals physical substance behind the definition: fibrils are dynamic structures that follow magnetic field lines but are denser and cooler than their surroundings. They are important elements of the active chromosphere. Future research on fibrils should therefore transcend the narrow objective of observing and explaining their appearance in Hα and bring to bear a full range of diagnostics. Particularly helpful would be: bi-dimensional (imaging) spectroscopy in temperature-sensitive visible lines, as well as Hα; UV/EUV imaging spectra from spacecraft; and magnetic measurements in chromospheric lines such as Hβ and He I 1083 nm. As many of these measurements as possible should be simultaneous. Such a range of observations would help to pin down not only the physical conditions within fibrils but the dynamic relationship of the fibril to the structure of the magnetic field and the coronal plasma in an active region.

Chromosphere: Heating Mechanisms

Mechanical heating

Chromospheres (and coronae) exist because of mechanical heating. Mechanical heating comprises all processes which convert nonradiative hydrodynamic or magnetic energy into thermal energy, that is, into microscopic random thermal motion. The physics of chromospheres (and coronae) is different from the physics of STELLAR ATMOSPHERES and interior layers, where the energy input is exclusively due to radiation, convection and thermal conduction. As observations show that the chromospheric emission depends strongly on the magnetic field, one subdivides the chromospheric heating processes into pure hydrodynamic mechanisms and magnetic mechanisms. Both types of mechanisms can be subdivided further into fast and slow processes. For the magnetic mechanisms the fast or wave mechanisms are called ac (alternate current) mechanisms and the slow mechanisms dc (direct current) mechanisms.

A mechanical heating mechanism consists of three processes, the *generation* of the energy carrier, the *transport* of this mechanical energy and its *dissipation*. Ultimately the mechanical energy comes from the nuclear processes in the stellar core. The energy generated there is transported in the form of radiation and convection to the stellar surface, where in the surface convection zone the mechanical energy is generated. The mechanical energy generation is due to the gas motions of the convection zone, which are largest in the regions of smallest density near the top boundary of that zone. Consequently the mechanical energy is generated in a narrow surface layer.

As current observations cannot tell with certainty whether a solar surface region is devoid of small-scale magnetic fields or not and because heating in current channels with diameters of meters cannot be resolved at the present time, it is difficult to identify a specific heating mechanism from the list of proposed processes. For an extensive list of proposed heating mechanisms see Narain and Ulmschneider (1996) and also the article on CORONAL HEATING MECHANISMS. Usually several mechanisms act at the same time. Surprisingly only by stellar observations (where the chromospheres are reduced to point sources) was one able to definitively identify acoustic waves as the important basic mechanism for stellar chromospheres. The reason for this is that for stars the effective temperature $T_{\rm eff}$ can be changed by 1 order of magnitude, the gravity g by 4, the metallicity by 3 and the rotation rate by 2 orders of magnitude. This greatly enlarges the range of theoretical predictions and thus permits crucial observations.

In the following subsections the necessity of mechanical heating, the zoo of mechanisms, the mechanical energy generation calculations, the observed mechanical heating rates and the possible total chromospheric heating picture are discussed in greater detail.

Necessity of mechanical heating

Consider a gas element in the chromosphere where flows introduced by the solar wind can be neglected. The total heating rate, that is, the amount of net heat per s, $\Phi_{\rm T}$ (erg cm^{-3} s^{-1}), flowing into the element across its boundaries, is given by

$$\Phi_{\rm T} = \Phi_{\rm R} + \Phi_{\rm J} + \Phi_{\rm C} + \Phi_{\rm V} + \Phi_{\rm M} = 0$$

as in dynamical equilibrium the chromosphere does not show time dependence. The terms on the right-hand side stand for radiative, Joule, thermal conductive, viscous and mechanical heating. A typical empirical chromospheric cooling rate from the standard solar model is $-\Phi_{\rm R} = 10^{-1}$ erg cm^{-3} s^{-1}. Consider a typical acoustic or magnetohydrodynamic disturbance in the solar chromosphere with characteristic values, size $L =$ 200 km, temperature $\Delta T = 1000$ K, velocity $\Delta v =$ 3 km s^{-1} and magnetic field perturbation $\Delta B = 10$ G. Using appropriate values for the thermal conductivity $\kappa_{\rm th}$, viscosity $\eta_{\rm vis}$ and electrical conductivity $\lambda_{\rm el}$ one finds (in erg cm^{-3} s^{-1})

$$\Phi_{\rm C} = \frac{\rm d}{{\rm d}z}\kappa_{\rm th}\frac{{\rm d}T}{{\rm d}z} \approx \frac{\kappa_{\rm th}\,\Delta T}{L^2} \approx 3\times 10^{-7}$$

$$\Phi_{\rm V} = \eta_{\rm vis}\left(\frac{{\rm d}v}{{\rm d}z}\right)^2 \approx \frac{\eta_{\rm vis}\,\Delta v^2}{L^2} \approx 1\times 10^{-7}$$

$$\Phi_{\rm J} = \frac{c_{\rm L}^2}{16\pi^2\lambda_{\rm el}}(\nabla\times B)^2 \approx \frac{c_{\rm L}^2\,\Delta B^2}{16\pi^2\lambda_{\rm el}L^2} \approx 7\times 10^{-5}$$

where $c_{\rm L}$ is the light velocity. It is seen that in the chromosphere $\Phi_{\rm C}$, $\Phi_{\rm V}$ and $\Phi_{\rm J}$ can be neglected relative to $\Phi_{\rm R}$ and that the main energy balance is between radiative cooling and mechanical heating. If mechanical heating were switched off then one would obtain radiative equilibrium, $\Phi_{\rm R} = 4\pi\kappa(J - S) = 0$. That is, in a radiative relaxation time scale of about a fraction of an hour radiative equilibrium would be reached. Here κ is the opacity, J the mean intensity and S the source function.

However, the heating rates $\Phi_{\rm C}$, $\Phi_{\rm V}$ and $\Phi_{\rm J}$ can become much bigger if the length scale L becomes very small. For acoustic waves as well as slow-mode MAGNETOHYDRODYNAMIC (MHD) and longitudinal MHD tube waves, this is accomplished by shock formation; for magnetic cases, by the formation of current sheets. Heating terms of the small L type are collected in the mechanical heating term $\Phi_{\rm M}$. Mechanical heating thus occurs when small scales form naturally.

The zoo of heating mechanisms

The *hydrodynamic mechanisms* consist of pulsational waves with periods larger than the acoustic cut-off period, $P > P_{\rm A} = 4\pi c_{\rm S}/\gamma g$ (where $c_{\rm S}$ is the sound speed and $\gamma = 5/3$ the ratio of specific heats), and acoustic waves where $P < P_{\rm A}$. These hydrodynamic mechanisms dissipate via shocks. The *magnetic mechanisms* are the acoustic-like slow-mode MHD waves and longitudinal

tube waves as well as the transverse and torsional Alfvén waves. The latter two wave types are difficult to dissipate in the chromosphere and numerous dissipation mechanisms, mode coupling, resonance heating, turbulent heating, have been studied. In addition magnetoacoustic surface waves are present which dissipate via mode coupling, resonant absorption and phase mixing. The dc mechanisms associated with magnetic field reconnection very likely operate at heights above the chromosphere. The so-called turbulent and explosive events seen in the C IV transition layer line are thought to be caused by such reconnection processes. For more details see Narain and Ulmschneider (1996).

Mechanical energy generation

Mechanical energy is generated by the turbulent gas motions in the convection zone. Numerical convection studies and observations indicate that the turbulent flows can be described by a Kolmogorov-type energy spectrum. Using such a spectrum where the rms turbulent velocity is provided from convection zone models (which depend on $T_{\rm eff}$, g and the mixing-length parameter α, where $\alpha = 2$ agrees well with observations), acoustic wave energy fluxes for the Sun and a large number of stars have been computed using the Lighthill–Stein theory (Ulmschneider *et al* 1996). Lighthill's theory of quadrupole sound generation is in excellent agreement with observations in terrestrial applications. Acoustic fluxes thus obtained are shown in figure 1. The Lighthill–Stein theory also provides acoustic frequency spectra which extend from the cut-off period $P_{\rm A}$ to about a factor 100 smaller with a maximum roughly at period $P_{\rm M} = P_{\rm A}/5$. For the Sun one finds typical values of the total acoustic wave energy flux of 1.7×10^8 erg cm^{-2} s^{-1} and period $P_{\rm M} = 60$ s, using a mixing-length parameter $\alpha = 2.0$.

The fluxes of longitudinal and transverse waves in magnetic tubes have been computed for the Sun by squeezing and shaking a tube model by external time-dependent turbulent flows at a given excitation height. Figure 2 shows the instantaneous and averaged generated longitudinal (top) and transverse (bottom) tube wave fluxes as function of time. The figure shows the very stochastic nature of the generation process. The wave energy generation occurs in spurts which is in good agreement with observations. The spurts are caused by sudden enhancements in the flow velocity. In figure 2 the same time-dependent turbulent velocity fluctuations were applied. For the Sun a typical average longitudinal wave flux of 1.5×10^8 erg cm^{-2} s^{-1} and for the transverse flux a value about 30 times higher were found with a flat maximum extending from $P_{\rm M} = 90$ s to larger periods. In view of the same acoustic wave flux inside and outside the tube one should realize that the gas density inside the tube is roughly by a factor of 6 smaller than the external density. Relative to this low density, the wave flux inside the tube is large, leading to rapid shock formation, but also to severe NLTE effects (departure from the thermodynamic equilibrium) which strongly modify the radiative losses.

Empirical mechanical heating rates

Standard empirical solar chromosphere models indicate that active regions (where magnetic fields dominate) need mechanical fluxes of $F_{\rm M} = 1.3 \times 10^8$ erg cm^{-2} s^{-1}, while quiet regions 1.4×10^7 erg cm^{-2} s^{-1}. These values have been multiplied by a factor of 2.3 to account for the line losses by Fe II.

Direct measurements of velocity fluctuations have been used to estimate the acoustic flux in the solar chromosphere. Because velocity fluctuations are observed as Doppler shift fluctuations of the cores of spectral lines, one must be careful to correct for seeing and for the effects of the line contribution function. Deubner (1988) finds $F_{\rm M} = 2 \times 10^7$, 1.2×10^6, 4.5×10^5 erg cm^{-2} s^{-1} at the heights 300, 800, 1500 km, respectively.

The emission cores of the Ca II H and K and of the Mg II h and k lines are reliable indicators of chromospheres. Plotting for many stars the empirical core emission fluxes in these lines versus $T_{\rm eff}$ one finds that the fluxes show a well-defined lower limit which extends e.g. for Ca II from $F_{\rm Ca} = 1 \times 10^7$ erg cm^{-2} s^{-1} for early F stars to 2×10^4 erg cm^{-2} s^{-1} for late M stars. This limit is called *basal flux line*. It has been shown recently that this basal emission can be reproduced by acoustic heating (Buchholz *et al* 1998). However, one finds that stars with the same $T_{\rm eff}$ and gravity g show different chromospheric emission and that this emission is larger when the stars rotate more rapidly. As rapidly rotating stars with a surface convection zone generate more magnetic fields via the dynamo mechanism it is clear that the excess heating is caused by magnetic heating mechanisms. A rapidly rotating star has more than an order of magnitude more chromospheric emission than the basal emission.

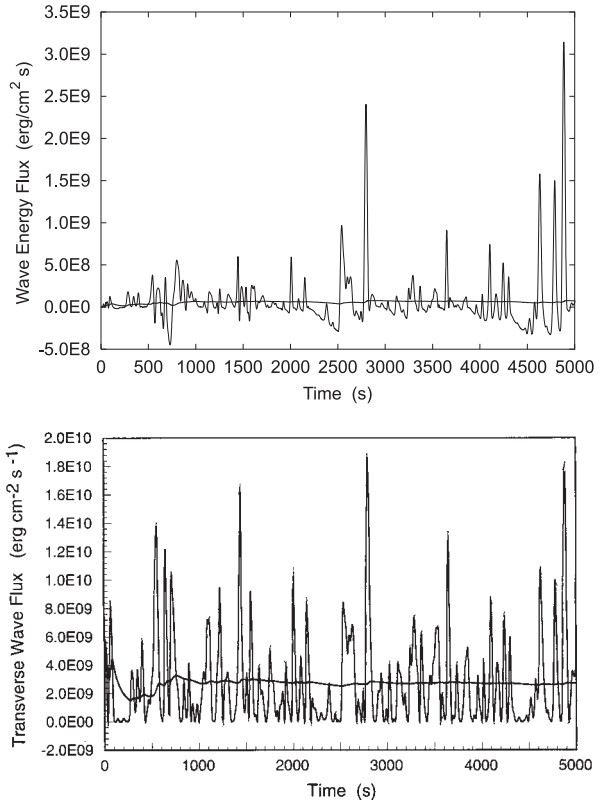

Figure 2. Instantaneous and average longitudinal (top) and transverse (bottom) MHD wave energy flux.

The total chromospheric heating picture

The successful reproduction of the basal flux line by acoustic wave heating models clarified that the fundamental heating process in chromospheres are acoustic waves. This mechanism operates independently of rotation. The faster a star rotates the more it is covered by magnetic fields which at photospheric and subphotospheric heights appear in the form of magnetic flux tubes. The fluctuating gas flows in the turbulent convection zone outside the tubes excite longitudinal, transverse and torsional MHD tube waves. By shock formation the longitudinal waves in the lower and middle chromosphere heat the flux tubes which explains the excess emission in the magnetic regions. With more tubes on the star, more tube wave energy is generated. The much more efficiently produced transverse waves have two problems: they suffer severely from leakage of the wave energy away from the tube and they are difficult to dissipate. Very likely they are responsible for the heating of the high chromosphere and the transition layer. Here stellar observations of the C IV line (Wood *et al* 1996) indicate that, in addition to wave heating, dc heating by microflares generated by reconnection events augments the Alfvén wave heating. These reconnection events are the result of slow horizontal convective motions (called foot-point motions) which lead to twisting and braiding of the magnetic flux tubes. Thus the convection zone is the source not only of ac heating but also of dc heating. The probably less efficiently generated torsional waves very likely traverse the chromosphere without dissipation and become important in the corona and in the stellar wind. An efficient three-dimensional simulation of the magnetohydrodynamics in stellar convection zones should in the future be able to completely explain the chromosphere phenomenon which, in absence of any input from interstellar space must, after all, be completely dependent on the interior of the star.

Chromosphere: Magnetic Canopy

The magnetic canopy is a layer of magnetic field which is directed parallel to the solar surface and located in the low CHROMOSPHERE, overlying a field-free region of the SOLAR PHOTOSPHERE. It has a field strength of the order of 0.01 T and covers a large area fraction of the solar surface. The magnetic canopy can be compared with the canopy of the rain forest: the tree-trunks correspond to the MAGNETIC FLUX TUBES that rise in the vertical direction from the photospheric level, while the spreading branchy foliage compares with the horizontally spreading magnetic field. As in the case of the rain-forest canopy, the magnetic canopy has its own life and is not readily accessible to observation.

The magnetic canopy can be observationally inferred from magnetograms taken in chromospheric spectral lines or, theoretically, from a magnetohydrostatic extrapolation of the easily observable photospheric magnetic field.

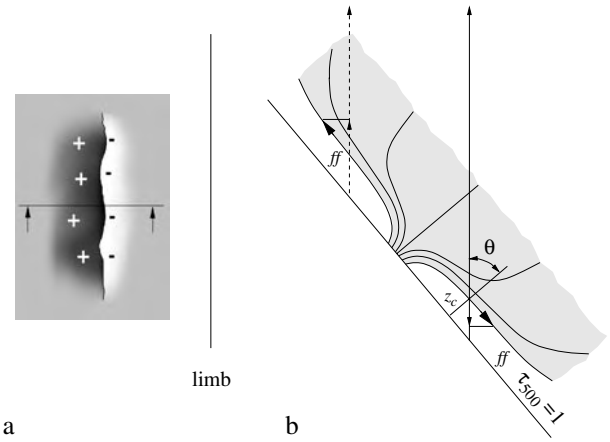

Figure 1. (*a*) Sketch of a chromospheric magnetogram near the solar limb and (*b*) the corresponding magnetic configuration. The base of the magnetic canopy is located at a height z_c above the solar surface.

Observational evidences of the magnetic canopy

At the beginning of the 1980s R G Giovanelli and H P Jones extensively studied the magnetic canopy, based on earlier suggestions and observational data by W C Livingston. They used magnetograms of the network field near the solar limb (see CHROMOSPHERE: NETWORK), taken in chromospheric spectral lines within the infrared and the visible wavelength range, e.g. the 854.2 nm triplet line of Ca II and the Mg I b_2 line at 517.3 nm. These magnetograms typically show a *polarity inversion* across a line that coincides with the limbward edge of a unipolar magnetic network field. (The magnetic network is seen in photospheric magnetograms, outlining the supergranule boundaries.) Towards disk center from the polarity-inversion line a diffuse field (dark area in figure 1(*a*)) extends well over a region which shows no magnetic field at the photospheric level and which has the same (normal) polarity as the magnetic network. On the limbward side this patch of normal polarity shows a fringe of opposite polarity. The polarity inversion and fringe pattern is a very common feature of chromospheric magnetograms of the network field near the limb. It also occurs in active regions and sunspots.

Figure 1(*b*) shows the magnetic structure that most naturally explains such a magnetogram. It shows the front elevation of the section indicated in figure 1(*a*). The normal to the solar surface (the height level at which the continuum optical depth at $\lambda = 500$ nm is unity ($\tau_{500} = 1$)) is inclined by an angle θ with respect to the line of sight, corresponding to an observation near the solar limb. Although the magnetic network field is fragmented and consists of many small-scale magnetic flux tubes, in figure 1(*b*), for clarity, it is represented by a single vertically oriented flux tube. At the network boundary the field is free to spread in the horizontal direction, thereby forming the magnetic canopy which, overlies the field-free region *ff*. The magnetic polarity inversion of the chromospheric magnetogram can now be readily understood as due to the canopy field in the following way. Lines of sight passing through the network field receive a magnetic field component toward the observer and so do lines of sight passing through the canopy field to the left (disk center) side of the network (dashed line of sight), explaining the extended diffuse network field. The canopy field to the right (limbward) side of the network, however, gives rise to a line of sight component of opposite direction (solid line of sight), which causes the fringe of opposite polarity. Note that the corresponding magnetogram of the magnetic network at the photospheric level would be of exclusively positive polarity. Towards the limb, the network fields apparently move closer together with increasing line of sight aspect angle θ, giving rise to an ever narrower *fringe pattern* of alternating polarity in the magnetogram.

By using a standard solar model atmosphere, the radiation transfer equation for polarized light is integrated along a line of sight that passes through the canopy field like the solid one indicated in figure 1(*b*). Assuming the atmosphere to be field free up to a height z_c and the canopy to consist of a homogeneous layer of magnetic field of strength B_c, the canopy height z_c can be derived from a comparison of the thus computed with the observed magnetogram signal. Since only the magnetic field close to the *canopy base* contributes substantially to the magnetogram signal (because of the rapid decrease of density and field strength with height), the assumption of a homogeneous, purely horizontally directed canopy field is a justifiable approximation. Such calculations have resulted in canopy heights of 600–1000 km above the solar surface (corresponding to the lower chromosphere) in quiet-Sun regions and as low as 200 km in ACTIVE REGIONS. Contrary to this, simple flux-tube models of the magnetic network show the canopy field to form in the *upper* chromosphere and the CORONA. Only models that allow for substantial differences between the atmosphere within the flux tube (*internal atmosphere*) and outside it (*external*

atmosphere) are capable of producing a low-lying canopy field. SUNSPOTS are also observed to produce a low-lying canopy field, which extends over a large distance beyond the penumbra (superpenumbra; see SUNSPOT PENUMBRA) with a canopy height of one hundred to several hundred kilometers. In this case, unlike to the network canopy, magnetic tension forces play a dominant role in keeping the canopy at low altitude.

The flux-tube model of the magnetic canopy

Given the magnetic field strength of the network field at the solar surface ($\tau_{500} = 1$), B_0, and the surface fraction occupied by this field, the magnetic filling factor f_0, the simplest model that can be constructed consists of an ensemble of static, rotationally symmetric, vertical flux tubes that are evenly distributed at the $\tau_{500} = 1$ level. It is usually assumed that at this level the field strength of the vertical component is constant across the flux tube, $B_z(r) = B_0 = \text{const.}$, and that the internal and external atmospheres are both plane parallel (no variation in lateral but only in the vertical direction). Given additionally the gas pressure p_g as function of height for the internal and external atmospheres, the magnetic field configuration can be computed for all heights, including the canopy and chromospheric region, by solving the magnetohydrostatic equation (see MAGNETOHYDRODYNAMICS).

A representative example of such a flux tube is shown in figure 2, indicating magnetic field-lines separating equal amounts of magnetic flux Φ. The flux-tube surface is distinguished by a discontinuity (in the case of an ideal plasma) in physical variables in such a way that the magnetic pressure, $p_{\rm mag} = B^2/2\mu$, exerted by the flux-tube surface field equals the difference in gas pressure between external and internal atmosphere, i.e.

$$B^2/2\mu|_{\rm surface} = p_{\rm g\,ext} - p_{\rm g\,int} \qquad (1)$$

where $\mu = 4\pi \times 10^{-7}$ V s A^{-1} m^{-1} is the magnetic permeability taken as that of free space. This equation is an immediate consequence of Ampère's law and is still valid in the presence of magnetic curvature forces. In the extreme case of a totally evacuated flux tube, $p_{\rm g\,int} = 0$, and we obtain $B_{\rm max}(z) = [2\mu\, p_{\rm g\,ext}(z)]^{1/2}$, which amounts to about 0.17 T at the solar surface level and to about 0.02 T at a height of 500 km. Because of the exponential decrease of the external gas pressure $p_{\rm g\,ext}$ with height, the magnetic flux tube expands, while keeping the total magnetic flux Φ constant.

It can be seen from figure 2 that the magnetic field in the outer parts of the tube becomes horizontal at some critical height, thereby forming the canopy field. This horizontally spreading field merges with the equal-polarity field of neighboring flux tubes, in which case it bends back and outward into the vertical direction again, or it connects with opposite-polarity neighboring tubes to form a loop-like structure. The first case is shown in figure 2, where the canopy field merges with the neighboring field of the same polarity at a height of

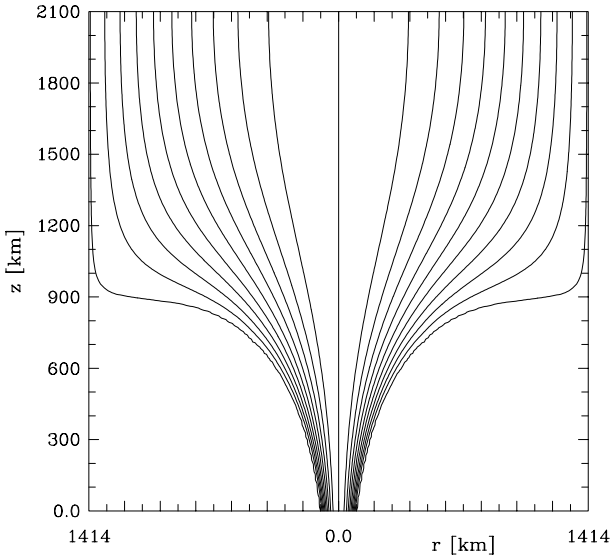

Figure 2. Magnetic flux tube. The field lines spread into a horizontally extending canopy field at a height of approximately 800 km and merge with the field of neighboring flux tubes of equal polarity at a radius of 1400 km.

900 km. The horizontal distance over which the canopy field stretches depends on the local filling factor, which varies between ≈0.2 (PLAGE regions) to 5×10^{-4} (quiet Sun). Thus, a canopy field may cover a large area of field-free photosphere of the quiet Sun. In figure 2 it stretches over only a moderate horizontal span (from 700 to 1400 km in a height region from 800 to 1100 km) owing to a filling factor of 5×10^{-3} that is ten times larger than that of a quiet-Sun region.

The height at which the canopy field sets in, the canopy height z_c, critically depends on the combination of external and internal atmosphere. A canopy field with a base height in accordance with observations ensues only when the flux-tube atmosphere shows a chromospheric temperature rise while the temperature in the external atmosphere continues to fall beyond the height of the temperature minimum of the flux-tube atmosphere. Under these circumstances, the gas pressure within the flux tube rapidly approaches the surrounding gas pressure at a critical point above the height of the temperature minimum. According to equation (1), this forces the flux-tube surface to spread in the horizontal direction because the finite surface field cannot reach beyond the critical height where $p_{\rm g\,ext} - p_{\rm g\,int} = 0$, irrespective of field strength or filling factor.

Is it possible that the external atmosphere remains cool up to the canopy base? An analysis of the solar spectral lines of the carbon monoxide molecule as well as radiative equilibrium models that include the effect of the CO molecule show that over a large fraction of the solar surface the temperature must strongly drop *below* the classical temperature minimum, so that the atmosphere *bifurcates* into a hot and a cool component near

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the height of the classical temperature minimum, which is at about 500 km above the solar surface (see CHROMOSPHERE: THERMAL BIFURCATION). It is very likely that the hot and the cool component represent the internal and external flux-tube atmospheres, respectively. Thus, the occurrence of the canopy field seems to be tightly connected with the thermal bifurcation of the solar atmosphere.

Consequences of the magnetic canopy

As a consequence of the thermal bifurcation, the atmosphere immediately below the canopy base is relatively cool ($\leq$4000 K) while the canopy itself may be already at chromospheric temperature, depending on the balance of heating and cooling. Hence, the canopy base represents a *thermal boundary layer*, which has important consequences for the formation of spectral lines in the lower chromosphere, such as the central emission core of Ca II H and K or Mg II h and k. The formation of these emission cores is suppressed by the cool atmosphere below the canopy base. On the other hand, since the flux-tube atmosphere shows a chromospheric temperature rise, the emission cores fully develop along the flux-tube axis and in its vicinity, the size of which depends on the expansion rate of the flux tube. This is in accordance with the observed enhanced chromospheric emission in network regions and the absence of it (with the exception of sporadic bright grains) in intranetwork regions (see SOLAR PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS). The model thus shows emission lines in the low chromosphere to be *spatially intermittent* on scales of about 1 arcsec and to be strongly correlated with the intense magnetic field at the photospheric level, both predictions being in good agreement with observation. The resonance lines of Mg II form slightly higher in the atmosphere than those of Ca II, probably mostly above the canopy base. Correspondingly, these lines show emission cores also in the intranetwork region.

A canopy field in conjunction with a spatially separate mass motion beneath the canopy (e.g. convective motion) may strongly influence the shape of Zeeman sensitive spectral lines when observed in polarized light (SOLAR MAGNETIC FIELD: MEASUREMENT and POLARIMETRY). The Stokes V profile of a spectral line (the difference between right-hand and left-hand circularly polarized light as a function of wavelength), which is anti-symmetric under normal conditions, may assume an extreme asymmetric shape depending on the velocity and the canopy height.

The magnetic canopy probably bears consequences for the formation and strength of acoustic shocks that result from upward traveling waves generated at photospheric and convection zone levels. These waves preferentially shock at around a height of 1 Mm, thus near the canopy base, giving rise to the Ca II H_{2V} and K_{2V} bright grains (see SOLAR CHROMOSPHERIC OSCILLATIONS). The precise emission properties of these grains are also expected to be modified by the presence of the magnetic canopy.

As another consequence of the magnetic canopy, the frequencies of solar acoustic p-mode oscillations of high modal degree are shifted to larger values. For a given mode, this FREQUENCY shift is proportional to the square of the canopy field strength, which is approximately proportional to the photospheric filling factor, f_0. This is a possible explanation for the variation of the frequencies of p-mode oscillations over the SOLAR CYCLE and their correlation with magnetic activity.

Chromosphere: Network

The chromospheric network on the Sun was discovered by HALE in 1892 with his newly invented spectroheliograph. It is a patchy pattern (Hale called it a 'reticuled structure') covering the solar disk outside active regions that appears when the Sun is imaged in spectral diagnostics formed in the CHROMOSPHERE (figure 1).

The network pattern has a honeycomb appearance at characteristic cell sizes of 10–40 arcsec and consists of small magnetic patches which outline, although incompletely, the borders of the supergranulation cells in the underlying photosphere (SOLAR PHOTOSPHERE: SUPERGRANULATION). Each magnetic patch measures a few arcsec and consists probably of a cluster of flux tubes that are either already physically merged at chromospheric heights (1000–5000 km above the photosphere) or appear merged due to radiation scattering (SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: OBSERVATIONS).

The chromospheric network is to high precision co-spatial with the magnetic network observed with magnetographs in the photosphere. The reason for the co-spatiality is the kilogauss field strength of the photospheric flux tubes. Such high field strength goes together with near-evacuation, therefore large buoyancy, and therefore radial (upright) orientation (SOLAR PHOTOSPHERE).

The network patches appear bright in chromospheric lines (the Ca II H and K resonance lines at $\lambda = 396$ nm and 393 nm, the inner wings of the hydrogen Balmer series Hα line at 656.3 nm, and many emission lines in the mid-ultraviolet). The observed brightness increases with the apparent magnetic flux density in the underlying photosphere, effectively measuring the spatial flux tube density. The intensity enhancement is presumably due to magnetism-related heating, but the precise mechanism has not been identified (CHROMOSPHERE: HEATING MECHANISMS).

The network pattern is dynamic on timescales of hours. Its evolution is governed by the continuous appearance of new magnetic field within supergranulation cells, the subsequent field migration to the cell boundaries imposed by the supergranular flows, further migration along the supergranular boundaries, and eventual field disappearance through dispersion, reconnection, subduction or rise into the upper atmosphere.

Composition

The magnetic flux tubes that make up the magnetic network are seen individually in the highest-resolution pictures of the photosphere. In particular, they are most sharply imaged in the Fraunhofer G-band around $\lambda = 430.5$ nm. This band is made up of molecular CH lines that brighten considerably, in not-understood fashion, at locations where strong-field flux tubes in intergranular lanes are dynamically interacting with the surrounding convective flows. The flux tubes show up on G-band filtergrams as tiny bright points with 0.1–0.2 arcsec diameter—just at the diffraction limit of the best telescopes (SOLAR PHOTOSPHERE: FILIGREE; SOLAR TELESCOPES AND INSTRUMENTS: GROUND).

The patches in the overlying chromosphere appear more diffuse, with grainy structure at 1–2 arcsec scale. In ground-based observations they are best seen when imaging the solar chromosphere in the cores of the Ca II H and K lines. These are the strongest spectral lines of the optically accessible part of the solar spectrum because calcium is an abundant element and most calcium particles reside in the singly-ionized ground state throughout the photosphere and low chromosphere. In addition, the network patches are well visible in the ultraviolet lines from the lower ionization stages of abundant elements such as CI and CII in the mid-ultraviolet. They remain visible in ultraviolet lines from higher ionization stages up to formation temperature $\approx 10^5$ K, and are also evident in Lyman α at $\lambda = 121.5$ nm (the strongest line in the solar spectrum).

More complex morphology is seen in Hα than in Ca II K because Hα has additional contributions from much higher layers, due to its high excitation energy. Only at high temperature and relatively high density does it become sufficiently opaque. When observed at Hα line center the network has dark extensions called mottles or, when they are longer than a few arcsec, fibrils (CHROMOSPHERE: FIBRILS). These extend into spicules when seen at the limb (CHROMOSPHERE: SPICULES). Such filamentary structures undoubtedly portray magnetic field topology and they may represent the lower parts of coronal loops (CORONAL LOOPS), but their behavior is very dynamic and clearly more complex than static loop models would predict. Static models of flux tube expansion with height (SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: THEORY) predict that at much lower levels the magnetic field should already funnel out to nearly homogeneous space filling (CHROMOSPHERE: MAGNETIC CANOPY). The observed mottle, fibril and spicule flows map the more vertical field lines since the gas moves freely only along the field. The more inclined flows do not reach as high.

The spatial coincidence with the magnetic network in the photosphere can be used to determine the magnetic polarity of the chromospheric network. It tends to be mixed-polarity over large areas in the quiet Sun and to become unipolar near active regions or to remain unipolar in the remains of previous active regions. Large unipolar areas also occur near the solar poles.

Topology and pattern evolution

The cellular appearance of the chromospheric network is incomplete, in contrast to the supergranulation cell boundaries observed on photospheric Dopplergrams. On low-resolution Ca II K spectroheliograms the cells are more easily outlined than on high-resolution Ca II K filtergrams, illustrating that the supergranulation flows do not produce field filling of the cell boundaries everywhere. In addition, there are mobile, small patches of field concentration within the supergranulation cells that haven't yet made

it to a cell boundary. It is likely that many of these mobile patches have recently emerged from below the surface.

The cell sizes of the chromospheric network are larger (32 Mm diameter) when determined with classical autocorrelation methods than when topological methods are used that identify cells from gradient diagnostics (13–18 Mm diameter). There seems to be no direct relation between cell size and magnetic content, although in non-quiet plage areas the field-free cells seem to be much smaller. The spatial cell characteristics are dominated by the spatial density of the upflow centers, as is also the case for the smaller-scale granulation (SOLAR PHOTOSPHERE: GRANULATION). Indeed, both granulation and supergranulation appear to form as bubbles starting from a 'seed' location, i.e. a center of outflow, and both are surface filling.

Magnetic patches originally emerge in bipolar ephemeral regions inside supergranular cells, and are subsequently transported to the supergranulation cell boundaries, where they stay confined. The motion of the magnetic concentrations can be described by a random walk in response to the continually evolving convective motions. On the granulation scale the granular buffeting makes magnetic concentrations move in a random walk with typical step lengths equal to a granular radius ($R \simeq 0.5$ Mm) and time steps equal to a granular lifetime ($T \simeq 10$ min). The flow patterns across supergranulation cells survive longer than the individual small-scale granular flows so that the patches are eventually collected in the supergranular boundaries by the supergranular outflows. They subsequently move along these boundaries and so outline the supergranular boundaries. This can be observed both for the chromospheric network on Ca II K filtergrams and high-resolution ultraviolet images, and on photospheric magnetograms.

Along the supergranular boundaries, the magnetic field appears concentrated in patches with an average magnetic flux content of 2.5×10^{18} Mx (Mx, Maxwell $= 10^{-8}$ Weber; 1 G $=$ 1 Mx cm^{-2}) varying from well below 10^{18} Mx to more than 15×10^{18} Mx per patch and with an exponential drop-off in frequency of occurrence. The observed Ca II K excess brightness $I_{\rm K}$ above the non-magnetic background ('basal flux') increases with the apparent magnetic flux density ϕ in the underlying photosphere according to the power law $I_{\rm K} \propto |\phi|^{0.65}$ (but with considerable scatter around this relation). Note that the apparent flux density is often confused with intrinsic solar magnetic field strength; it is primarily a measure of the spatial density of unresolved flux tubes with intrinsic field strength $|\boldsymbol{B}| \approx 1400$ G over the angular resolution element of the telescope.

On the supergranulation scale the cell pattern evolution causes another random walk with typical step lengths equal to a supergranular cell radius ($R \simeq 6 - 9$ Mm) and typical time steps equal to the characteristic supergranular lifetime ($T \simeq 24$ h).

While diffusing along supergranular boundaries, the flux patches may interact with one another. When field concentrations of opposite polarity meet, they may cancel against each other, i.e. vanish from sight. This may be due to actual field reconnection, but may also indicate that magnetic fields move upwards or downwards through the observed layer, in the form of small vertical loops with their apex pointed downward or upward respectively. When patches of the same polarity meet, flux merging may be observed. The reverse process, fragmentation, is also seen.

The overall exponential flux distribution function can be described by a 'magnetochemistry' model that describes the emergence of new concentrations, fragmentation into pieces, and disapperance through cancellation or merging. Taking the frequencies of these processes into account, the maximum lifetime of an individual field concentration is estimated to be no more than about 40 h. Thus, the fine structure of the quiet network cannot be recognized after a longer time span.

Dynamical properties

The precise co-spatiality between the chromospheric network and the photospheric magnetic field and the power-law relation between network brightness and apparent flux density (primarily measuring spatial flux tube density) strongly suggest that a magnetically dominated heating mechanism operates in or along the kilogauss flux tubes that make up the network (CHROMOSPHERE: HEATING MECHANISMS). However, many attempts have failed to find wave modes that would betray kinetic energy transfer from the photosphere where the flux tubes are buffeted by the granular flows up to the chromospheric heights where wave dissipation might contribute the heating that is required to explain the observed brightness. So far, all network oscillation studies have only identified rather slow periodicities, 5 min or longer. This result is in stark contrast with the roughly 4 to 2 min acoustic waves that are ubiquitously present in the internetwork regions. It is not even clear whether the observed slow modulations describe wave modes (such as breaking internal gravity waves) or just random motions enforced by the foot-point swaying. Thus, the actual mechanism through which the network patches are bright, while undoubtedly due to dynamical flux tube physics, is yet to be identified.

Chromosphere: Spicules

As early as 1877 Father Secchi described the jet like, elongated structures in the solar chromospheres which were named spicules by Walter Orr Roberts in 1945. They are observed in the optical chromospheric emission lines of hydrogen (especially the 656 nm Hα line), ionized calcium (especially the 393 nm and 397 nm H and K lines) and helium lines (especially the 588 nm and 1083 nm neutral helium lines). Figure 1 shows a series of images of the CHROMOSPHERE taken at different wavelengths in the Hα line showing the spicular structures. Except for the lowest heights above the solar limb, up to 1500 km, the spicules are clearly visible. Typical spicule properties are: width 900 km, average height 8000 km, lifetime 15 min apparent velocities 25 km s^{-1}.

From images like the one in figure 1 one derives the spatial properties of the chromosphere and its structure. Most or all of the chromospheric emission in these lines appears to come from spicules, so that it is fair to say that the solar chromosphere, at least at heights exceeding 1500 km above the photosphere, consists of spicular material. The decrease of average chromospheric brightness with height is the result of the decrease of the individual spicule brightness and of the number of spicules with height. When observed in the Hα line, the line most used, we observe an average height of spicules of 8000 km, somewhat less near the solar equator, more at the poles. It should be noted, however, that their upper boundary is not well defined, so that the observed height depends on the observing conditions. Individual spicules can extend significantly higher with heights above 10 000 km being observed. In the literature one finds references to so-called 'super-spicules' especially in the discussion of solar limb observations made in far-ultraviolet lines like the ionized helium line at 30.4 nm. Super-spicules are significantly larger than spicules; they are structures which in their properties lie between spicules and transient solar prominences (SURGES). Not included in the present context, they will be briefly discussed at the end of this section. The width of spicules is observed to average 900 km, which is probably an upper limit since it is uncorrected for the imaging effects of the Earth's atmosphere (SEEING).

Dynamics

The dynamics of spicules is most interesting. In their initial appearance they appear 'geyser-like' in the sense that there is an upward surge of material with velocities reaching 25 km s^{-1} lasting for some 5 min, but with a path which is frequently slanted with respect to the local vertical direction. After reaching a typical maximum height of 9000 km in 5 min, the ejection stops. It is followed by a fading of the spicule brightness or a return of the emitting material to the photosphere. On balance many more spicules appear to go up than come down. The total life cycle for those that descend is about 15 min. Since the spicular material is largely ionized, motions tend to follow the direction of the magnetic field lines. The spicular orientations and motions are therefore a good proxy for the magnetic field structure pattern in this part of the solar atmosphere. Direct measurements of the magnetic field strengths by means of the Zeeman, or possibly Hanle effect are not available yet (see SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). Although there are significant temporal and local spatial variations in the orientations, there are clear changes in the average orientations of spicule directions, and hence magnetic fields, with solar latitude. Near the solar equator the orientations, although on the average vertical, vary greatly from spicule to spicule. Near the poles the orientations are more uniform, mostly close to vertical, but sometimes inclined systematically. In polar regions the inclination appears to follow the orientations of coronal plumes. Because of the systematic group behavior of spicules there, the patterns are sometimes referred to as 'porcupine' or 'wheat field' configurations.

Astronomers are always concerned that the apparent motions seen in motion pictures like those of the Hα chromosphere might not correspond to real motions. Apparent motions can result from other effects, like temporal changes in atomic excitation conditions. The only way of checking the reality of the motions is by means of observations of the Doppler shift of the spectral line. This is a tricky thing to do, however, since the apparent, 'proper motions' occur in the plane of the sky whereas the Doppler shift correspond to line-of-sight motions. The comparison therefore is statistical, and requires knowledge of the varying tilts of spicules. Observations to date, taking these considerations into account, have indeed shown the apparent motions to be actual material motions. Doppler shifts appear to vary across spicules resulting in a tilt of the spectrum emission lines. These variations are often interpreted in terms of a rotation of spicules.

Physical properties

In addition to telling us about velocities, spectral analysis of the spicular emission provides important information about the physical conditions in spicules. Spectral observations are available in a number of different lines: the hydrogen Balmer lines (Hα through Hε), neutral helium lines (D3 line at 588 nm, 1083 nm line), and the ionized calcium lines at 393, 397, 850 and 854 nm). The observed emission of these lines indicate temperatures in the vicinity of 15 000 K, probably lower (<10 000 K) at heights below 2000 km, and electron densities decreasing from 1.5×10^{11} cm^{-3} at $h = 2000$ km to 3×10^{10} cm^{-3} at $h =$ 10 000 km. At the lower heights spicules are embedded in the what is normally referred to as the chromosphere–corona transition region. At the greater heights they are embedded in the million degree CORONA itself, but there must be a local transition region between each spicule and this corona. Nothing is known about these local transition regions. Future high-resolution observations from space of higher temperature emission lines in the ultraviolet (for example the CIV lines at 155 nm and the

helium Lyα line at 30.4 nm) can be expected to clarify that. The electron pressure in spicules at a height of 8000 km equals 0.09 dyn cm^{-2} as compared to 0.02 dyn cm^{-2} in the surrounding corona. The difference is large enough that it may be real, indicating possibly a significant overpressure in the chromospheric spicules. In addition one derives from the width of the spectral lines in spicules a non-thermal broadening of about 20 km s^{-1}, part of which may result in a turbulent pressure. An isolated magnetic field of only 1 G results in a dyn cm^{-2} magnetic pressure of 0.04 dyn cm^{-2}, a variation of 1 G in an average field of, for example, 12 G in a variation of 1 dyn cm^{-2}. Except for channeling the spicular motion, for which the field has to be significantly larger than 1 G, the magnetic field variations between spicule and the surrounding corona have to be less than 1 G, with the magnetic field strength variation, if any, being less in spicules.

This sensitivity in the pressure balance to small changes in the magnetic field strengths also points out large effects that the magnetic field can have on the dynamics of spicules. Quite a large number of theoretical models exist for the origin of spicules, all involving magnetic field effects. Because of the similarity in their dimension to that of the solar convection cells which are observed at the solar surface as GRANULATION, and because of the similarity in birth rates of spicules and granules within the higher magnetic field concentrations seen at the solar supergranule boundaries (see later in this section) it has been suggested that spicules are the result of the convection–magnetic field interactions. What is clearly needed are improved observations of spicule spectra and images, including higher spatial resolution observations of their velocities and, if possible, magnetic fields. Also, observations of spicules as observed in projection against the solar disk are invaluable. That is the main topic of the following discussion.

Appearance against solar disk

When observing structures like PROMINENCES or spicules in the higher solar atmosphere against the solar disk one might see those structures either as dark features in absorption or as bright structures in emission. Such structures are dark when the amount of background radiation from the solar disk that is absorbed is larger than the amount emitted by the structure itself. The ratio of the emission to absorption coefficient in the structure is referred to as the 'source function' of the structure, or in short S. A structure is bright when S exceeds the background intensity I, dark when it is less. The contrast depends on the optical thickness τ, so that the intensity difference ΔI from the background equals: $\Delta I = (I - S)(1 - e^{-\tau})$. This simple model of the visibility of structures overlying the bright solar background is frequently referred to as the 'cloud model'. The same model actually holds for terrestrial clouds and for any other similar configuration anywhere. For the conditions existing in the solar atmosphere the source function S can be taken as wavelength and direction independent. The background intensity is a function of wavelength (Hα is a strong Fraunhofer absorption line) and of position on the solar disk (solar limb darkening). It is therefore quite likely that the sign of the contrast of spicules when seen in projection against the solar disk changes with position in the Fraunhofer line and with disk position. With the physical conditions in spicules described earlier, one might expect spicules to be dark when seen in the line wings for most of the solar disk. Near the core of the H line and at the extreme limb one expects bright contrast structures. Right at the solar limb, where the disk brightness falls off rapidly and actually vanishes outside the limb, the expected behavior of spicule contrast is very complex. It is therefore very difficult to trace the spicules from outside the limb back onto the solar disk in order to unambiguously directly identify disk structures with spicules. It is, however, generally accepted that the dark, narrow, elongated 'mottles' seen in monochromatic images in the wings of the Hα line (see figure 2) are to be identified with chromospheric spicules in projection on the solar disk. The $(1 - e^{-\tau})$ term in the cloud model is also wavelength dependent because the optical thickness τ is. It does not affect the sign of the contrast, only its magnitude.

Given this identification of spicules as seen against the solar disk, one can determine a number of other important

Figure 2. Monochromatic image of the Sun in the wing of the hydrogen Balmer α line of a region near the solar limb. The lower half of the image shows a small active region. Closer to the solar limb in the upper half of the image one recognizes the patterns of dark elongated mottles which are commonly identified with the chromospheric spicules as observed outside the solar limb. Note that they are arranged in 'hedgerow' or 'porcupine' like patterns which form the so-called chromospheric network. This network, foreshortened when seen near the solar limb, surrounds the supergranulation convection cells described elsewhere. (Courtesy R B Dunn, National Solar Observatory at Sacramento Peak.)

parameters. It is clear from images like those shown in figure 2 that spicules are not uniformly distributed across the solar disk. They are located in the so-called chromospheric network which borders the photospheric granulation cells (see CHROMOSPHERE: NETWORK). Although it is estimated that there are about 10 times fewer spicules than granules on the Sun, the number density of granules and spicules, as well as their birth rate, within these network areas are comparable. This suggests a physical relation between the granulation structure and spicule occurrence in these regions, with the well known local solar magnetic field enhancement in these network elements of about 100 G almost certainly playing an important role. However, attempts at establishing observationally such a connection have so far failed. The suspicion is that limited spatial resolution and possibly spicules originating well above the photosphere may be the cause of these failed attempts. But it may be, of course, that there is no such connection either with the granules themselves or with the intergranular lanes.

Role of spicules

What role do spicules play in relation to other solar aspects? From the physical parameters it is easy to estimate the kinetic energy flux and mass flux in the combined spicules. In the upward moving spicules the kinetic energy flux is negligible compared with other energy transfers to and from the corona. It is a factor of 100 less than, for example, the conductive energy losses downward from the solar corona. The mass flux is a totally different matter. In the upward moving phase the spicule mass flux exceeds the mass loss of the solar corona through the SOLAR WIND by two orders of magnitude. In that sense spicules may be of broader interest rather than being a phenomenon of only parochial interest.

No generally accepted magnetohydrodynamical model exists for spicules. A number of models have been proposed using a variety of physical mechanisms including different kinds of wave phenomena, instabilities, magnetic reconnection, etc based on velocity and magnetic fields associated for example with granules and supergranules. They all claim to explain many of the observed spicule properties. Improved observations of spicules will be needed to distinguish between these models. New tools like solar adaptive optics and high-resolution UV observations which are likely to be available in the near future are likely to clarify the situation.

There are larger structures visible especially well in ultraviolet lines like the He^+ Lyα line at 30.4 nm which are similar in behavior to spicules. They are referred to as 'super-spicules' and are mostly seen at high solar latitudes. Attempts to relate these structures to Hα images of the chromosphere and prominences have failed. Occasionally exceptionally long spicules in Hα are also seen in the solar polar regions. They have been called 'macro-spicules'. Little is known about the behavior and origin of either of these larger structures.

Chromosphere: Thermal Bifurcation

Thermal bifurcation refers to the existence of 'cool clouds' of gas ($T < 3500$ K) at high altitudes in the solar atmosphere, within what was thought to be a uniformly hot ($T \sim 7000$ K) CHROMOSPHERE. It also refers to a cooling instability, promoted by carbon monoxide molecules, which operates in places where the chromospheric mechanical heating is weak. The cool clouds were discovered through the anomalous darkening of strong 4.7 μm CO absorption lines near the extreme limb; first recognized in the early 1970s, and more recently confirmed in the surprising off-limb emissions of the infrared CO bands. Because carbon monoxide is both the principal diagnostic of the cool gas and a possible contributor to its formation, the low-temperature protrusions into the chromosphere have been deemed the 'COmosphere'. The underlying cause of the cool gas and how much of the volume of the low chromosphere it might occupy remain controversial.

Background

In the early 1970s, R W Noyes and D N B Hall reported curiously depressed brightness temperatures of carbon monoxide absorptions in infrared (4.7 μm) spectra taken close to the edge of the solar disk. The 'cool cores' of the CO lines—as low as 3700 K—were surprising because they were as cool as the coldest temperatures thought to occur in SUNSPOTS, arguably the chilliest features of the solar atmosphere. Noyes and Hall also noted striking intensity fluctuations of the infrared CO lines, presumably in step with high-altitude compressions and rarefactions caused by the global p-mode oscillations.

At the time, a controversy had developed whether the minimum temperature at the base of the chromospheric temperature inversion was as hot as the 4400–4500 K indicated by Ca II 393 nm and Mg II 279 nm or instead the 4200 K suggested by continuum intensities in both the far-ultraviolet and submillimeter regions. During the $T_{\rm min}$ debate, the curious discovery by Noyes and Hall was dismissed as an unimportant oddity. The authors themselves had attributed the dark cores of the strong CO lines to an effect connected with the narrow, cool subduction lanes of the photospheric granulation pattern. In many minds, the anomalous CO temperatures thus were associated with a small-scale phenomenon of the SOLAR PHOTOSPHERE, of questionable relevance to the global atmosphere, and certainly not to the overlying chromosphere.

In the late-1970s, a powerful new optical–infrared instrument—the 1 m Fourier transform spectrometer (FTS)—was commissioned at Kitt Peak. The $T_{\rm min}$ debate had rekindled interest in alternative ways to trace the thermal stratification of the outer photosphere. T R Ayres (a proponent of the 'hot' $T_{\rm min}$) and L Testerman revisited the anomalous extreme-limb behavior of the CO lines, confident that the high-precision FTS measurements would bring the CO $\Delta v = 1$ bands into agreement with other $T_{\rm min}$ proxies. However, not only did Ayres and Testerman confirm the earlier result of Noyes and Hall, but also they concluded that the CO anomaly could be explained most naturally by adding a new layer to the solar atmosphere; a pervasive cold component overlapping the lower reaches of the traditional hot chromosphere.

In parallel, Ayres offered an explanation for the out-of-character cool high-altitude gas. His 'thermal bifurcation' mechanism was an elaboration of the key role of CO surface radiative cooling—something like a reverse greenhouse effect—originally described independently by T Tsuji and H R Johnson in the context of the photospheres of red giant stars. The idea is as follows. The vibration–rotation transitions of CO very efficiently convert gas collisional energy into infrared photons. Those photons that escape the region carry away thermal energy and thus cool the gas. When there is little or no mechanical heating in the outer layers of the photosphere, the strong surface cooling in the 4.7 μm CO bands drives the gas to a low-temperature state, balancing the mild heating in the H^- continuum (optically thin absorption of mainly visible photons from the background photospheric radiation field). If a small amount of mechanical heating is introduced on top of the slight radiative component, however, the gas will warm and the CO molecules will begin to dissociate. The loss of CO reduces the cooling, leading to additional warming and further dissociation. The ensuing thermal runaway ('heating catastrophe') halts only above about 6000 K, where partial ionization of hydrogen liberates enough electrons to collisionally energize high-temperature cooling species such as Ca^+ and Mg^+. If the mechanical heating then is removed, the gas first cools down to the H^- boundary temperature ($\sim$4900 K), at which point CO begins to form, which cools the gas further; more CO forms, and so forth, leading to a 'cooling catastrophe' that returns the region to the low-temperature branch of the 'bifurcated' energy balance.

In this view, the outer atmosphere of the Sun can exist in two rather different thermal states—one cold, the other hot—depending on the amount of mechanical energy deposited locally. The thermal bifurcation mechanism naturally operates only at high altitudes; once the CO $\Delta v = 1$ bands become optically thick, the infrared photons are trapped in the source region and the radiative cooling is strongly suppressed.

In the thermal bifurcation picture, the classical hot chromosphere is confined to small-scale overheated structures bathed in a pervasive cool high-altitude layer close to radiative equilibrium. Figure 1 is a cartoon contrasting the historical and new views of the solar outer atmosphere.

Photosphere–chromosphere interface

The classical picture, illustrated in the left-hand panel, is a plane-parallel stratification; a hierarchy of distinct layers, controlled by different energy budgets, but through which the temperature runs smoothly. The layered atmosphere represents the idealized response of a hydrostatically
